The explosives industry requires a porous, low-density (LD) ammonium nitrate that can be impregnated with oil. This LD ammonium nitrate can be produced by spraying with hot air in two-component nozzles into a revolving drum heated with hot air. However, porous LD ammonium nitrate can also be produced by prilling [25]. An ammonium nitrate melt of relatively low concentration (96 %) is sprayed in the prilling tower, and the prilled product is then carefully dried with hot air in two successive dryers. The product contains 0.2 % of water and has a powder density of 800 g/L and a porosity of 33 vol%.

1.4. Grain Stabilization and Surface Treatment (Conditioning)

The crystal transition point at 32 °C and the hygroscopicity adversely affect the storability of the granulated ammonium nitrate. A temperature of 32 °C can often be exceeded, particularly during transport and storage in warm countries: the granules lose strength and finally disintegrate into dust. The modification change and other solid-phase reactions can be inhibited by low moisture content and additives that act as internal stabilizers. The additives are added to the melt before it is sprayed. Examples of additives are anhydrous $CaSO_4$ [26], $H_3BO_3 + (NH_4)_2HPO_4 + (NH_4)_2SO_4$ [27], ammonium and potassium polyphosphate [28], and nucleating agents, such as silica gel [29], metal oxides, or kaolin [30]. $Mg(NO_3)_2$ [31] and $Al_2(SO_4)_3$ [32] are important stabilizers. In gen-

eral, the stabilizers also inhibit the reaction between NH_4NO_3 and $CaCO_3$, which forms the highly hygroscopic calcium nitrate.

Usually, the ammonium nitrate granules are prevented from caking during storage by a final surface treatment (coating). The earlier practice of powdering with inorganic substances to separate the grains mechanically has mostly been replaced by treatment of the grain with effective organic surfactants, such as cationic long-chain fatty amines or anionic alkylarylsulfonates. Anticaking effectiveness is enhanced by addition of nonionic organic substances, such as polyethylene (PE) waxes [33] or paraffins. The fatty amines are applied as melts or oil solutions. One process [34] is multistage: in the first stage the fertilizer granules are coated with a uniform, compact layer of molten $C_{12}-C_{18}$ alkylamine. In the second stage they are cooled to convert the amine into the solid state. In the third and final stage, they are provided with a thin coating of mineral oil.

1.5. Transport Regulations

National and international regulations governing the transport of ammonium nitrate and its mixtures are being based to an ever-increasing extent on the classification of the "United Nations Committee of Exports on the Transport of Dangerous Goods" [35].

A number of ammonium nitrate-based products are to be transported according to regulations for Class 5.1, e.g., technical ammonium nitrate UN No. 1942 or the various ammonium nitrate fertilizers UN No. 2067 – 2070. Main criteria for this class are concentrations of the components and a strict limitation of combustible substances. Mixtures with high concentrations of ammonium nitrate or combustible materials are not allowed to be transported unless they are clearly defined as explosives, Class 1. Mixtures with ammonium nitrate contents below the limits are considered nonhazardous, with the exception of one group that may be subject to self-sustaining decomposition (smoldering) when heated. This group of AN fertilizers is classified in Class 9 (UN No. 2071).

Regulations for the marine transport of the above classes are given in the IMDG Code (Inter-Governmental Maritime Consultant Organisation, London) on pages 5014, 5015, and 9013.

The international regulations for road and rail transport, ADR (Accord européen relatif au transport international des marchandises dangereuses par route) and RID (Règlement international concernant le transport des marchandises dangereuses par chemins de fer) have brought the ammonium nitrate products also into Class 5.1, Subdivision 6. The criteria of composition correspond closely to those of the IMDG Code.

Transport on inland waterways is regulated by ADN (Accord européen relatif au transport international des marchandises dangereuses par voie de navigation interieure) and for the Rhine by ADNR. Although ammonium nitrate products are still placed in a special class (Class III c), these regulations are being redrafted to harmonize the classification.

1.6. Safety

Although stable under normal conditions, ammonium nitrate undergoes a number of decomposition reactions at elevated temperature [36], [37]. The following are significant:

1) Endothermic dissociation and lowering of the pH above 169 °C.

$$NH_4NO_3 \longrightarrow HNO_3 + NH_3 \quad \Delta H = +175\ \text{kJ/mol}$$

2) Exothermic elimination of N_2O on careful heating at 200 °C.

$$NH_4NO_3 \longrightarrow N_2O + 2\,H_2O \quad \Delta H = -37\ \text{kJ/mol}$$

3) Exothermic elimination of N_2 and NO_2 above 230 °C.

$$4\,NH_4NO_3 \longrightarrow 3\,N_2 + 2\,NO_2 + 8\,H_2O \quad \Delta H = -102\ \text{kJ/mol}$$

4) Exothermic elimination of nitrogen and oxygen, accompanied by detonation.

$$NH_4NO_3 \longrightarrow N_2 + 1/2\,O_2 + 2\,H_2O \quad \Delta H = -118.5\ \text{kJ/mol}$$

Pure ammonium nitrate, highly concentrated hot solutions of ammonium nitrate, some mixtures of ammonium nitrate, and fertilizer ammonium nitrate, unless stabilized, are included

among explosives detonated by shock waves. Although the heat released is small in comparison with that of an explosive such as hexogen, there are serious risks attending the storage of large quantities. For example, hydrogen ions, chlorides, and heavy metals catalyze the decomposition. The heating of contaminated and tamped ammonium nitrate is particularly dangerous. Following the disasters in Brest and Texas City (1947) [38], [39], where whole ships' cargoes of wax-coated fertilizer ammonium nitrate exploded as a result of fires, the content of inflammable substance has been universally limited to 0.2 % or 0.4 %. In the Federal Republic of Germany, special procedures have been introduced under the *Arbeitsstoffverordnung* (Working Materials Act) [40] for storage, loading, and transport of ammonium nitrate and products containing ammonium nitrate. For example, the storage of ammonium nitrate capable of detonation is permitted only in small batches in specially equipped storage sites. There are similar regulations in many other European countries, whereas in the United States, France, Norway, and England the storage of relatively large amounts is permitted under some conditions.

In Germany inert materials, such as limestone powder, dolomite, or precipitated calcium carbonate, are added to ammonium nitrate for fertilizer use (calcium ammonium nitrate). Such fertilizers, containing no more than 80 % ammonium nitrate, no more than 0.4 % combustible constituents, and no less than 18 % magnesium or calcium carbonate, rate as nondetonatable. The sensitivity of ammonium nitrate and its mixtures to shock is determined by tests in which a sample tamped in a closed steel tube is exposed to a shock [36], [40], [41]. In addition, oil retention [41], a measure of porosity, is a basis for assessing the safety of ammonium nitrate.

To summarize:

1) If products containing ammonium nitrate have solidified during storage, they should not be broken up by blasting
2) Products containing ammonium nitrate must be stored separately from oxidizable, inflammable materials
3) If ammonium nitrate must be heated (during production, evaporation, etc.), the quantity must be kept small and catalysts avoided

1.7. Uses

Ammonium nitrate (AN) is used mainly as fertilizer, either pure, diluted, or in multinutrient mixtures. It is used with urea in liquid fertilizers, which are important in the United States, Eastern Europe, and France.

In the United States, the United Kingdom, and France, ammonium nitrate having a nitrogen content of 33.5 % and higher is used in large quantities in agriculture. A fertilizer containing 32.5 % N is also used in the United States. In the Federal Republic of Germany, ammonium nitrate is used in mixtures with lime, dolomite, ammonium sulfate, or potash. Among these calcium ammonium nitrate is particularly important (→ Fertilizers).

Calcium Ammonium Nitrate (CAN). Ammonium nitrate solution (ca. 95 – 97 %) can be granulated with finely divided calcium carbonate from crushed limestone or from the conversion of calcium nitrate. The granules obtained are dried, cooled, screened, and treated to avoid caking. The reaction of ammonium nitrate and limestone to form hygroscopic calcium nitrate is prevented by additives, such as $(NH_4)_2SO_4$, $MgSO_4$, and $FeSO_4$. In Germany, the nitrogen-content of calcium ammonium nitrate was increased in stages from the original level of 20.5 % N to the present level of 27.5 % N. The upper limit under the regulations of the European Economic Community is 28 % N.

Ammonium Sulfate Nitrate (ASN). The mixed sulfate – nitrate fertilizer is produced by adding ammonium sulfate to approximately 95 % ammonium nitrate solution [42] or by neutralizing HNO_3–H_2SO_4 mixtures with ammonia [43]. A slightly hygroscopic product is obtained after granulation. It is a mixture of the double salt $2\,NH_4NO_3 \cdot (NH_4)_2SO_4$ and a little ammonium sulfate [44], containing 26 % N for < 45 % ammonium nitrate. The mixture tends to harden during storage as a result of further reactions. This can be prevented by addition of salts of Mg, Fe, or Al [45].

Potassium Ammonium Nitrate. Potassium ammonium nitrate is produced in the same way

Table 4. Production of fertilizer NH_4NO_3, 10^6 t N, 1981

	Production	Import	Export
Western Europe	4.8	1.0	0.9
Eastern Europe	6.3	–	0.4
North America	1.9	0.1	0.1
South America	0.3	–	–
Africa	0.5	0.2	–
Asia and Oceania	1.0	0.1	–
Total	14.8	1.4	1.4

as ammonium sulfate nitrate, except that a potassium salt (the chloride or sulfate) is added to give, e.g., 20–0–20 ($N–P_2O_5–K_2O$) fertilizer.

Nitromagnesia. A fertilizer can be produced from ammonium nitrate, ammonium sulfate, and magnesium compounds, such as dolomite, magnesium carbonate, or magnesium sulfate. For example, such a fertilizer may contain 20 % N, 8 % MgO, and generally 0.2 % Cu.

Other Uses. Safety explosives for mining are produced from ammonium nitrate (AN). It is suitable by virtue of its low explosion temperature. In mixtures with NaCl, the explosion temperature is not high enough to set off the much-feared fire damp. For safety explosives, ammonium nitrate must have the following qualities:

NH_4NO_3 content		99.0 %
Ignition residue	max.	0.2 %
Chloride	max.	0.1 %
Nitrite	max.	0.1 %
Sulfate	max.	0.1 %
Water insoluble	max.	0.1 %

In many cases, safety explosives are also based on the reciprocal salt pair $NaNO_3 + NH_4Cl \rightleftharpoons NH_4NO_3 + NaCl$. Where greater explosive power is required, as in mining (rock explosives), porous prilled ammonium nitrate containing approximately 6 % diesel oil is used (ANFO = ammonium nitrate fuel oil) (→ Explosives).

To a lesser extent, ammonium nitrate is used to produce dinitrogen monoxide, N_2O. The salt must be 99.5 % NH_4NO_3 and be free of organic materials, iron, chlorides, and sulfates.

1.8. Economic Aspects

Table 4 provides a synopsis ofthe production of ammonium nitrate for fertilizers in various countries.

2. Ammonium Sulfate

Ammonium sulfate [*7783-20-2*], $(NH_4)_2SO_4$, was produced industrially in the 19th century, mainly from the ammonia in coke-oven gas. At the beginning of this century ammonia was synthesized on an industrial scale, and ammonium sulfate became a widely used fertilizer. Its importance, however, has steadily declined with the development of more concentrated nitrogen fertilizers. Small quantities are used for industrial purposes. Since about 1960, ammonium sulfate has been produced to an increasing extent as a coproduct in organic syntheses. In some countries ammonium sulfate is produced from gypsum.

2.1. Properties

Ammonium sulfate, M_r 132.14, d_4^{20} 1.77, average specific heat capacity 1.423 $J\,g^{-1}\,K^{-1}$ between 2 and 55 °C, rhombic bipyramidal. The size and habit of the crystals can be affected significantly by substances in the crystallizing solution, and this can be an important factor in commercial production.

Ammonium sulfate cannot be melted at atmospheric pressure without decomposition, releasing ammonia and leaving bisulfate. However, the ammonia vapor pressure of pure, anhydrous ammonium sulfate is effectively zero up to 80 °C. Above 300 °C, decomposition gives N_2, SO_2, SO_3, and H_2O in addition to ammonia.

The solubility of ammonium sulfate in water is shown in Figure 11. The salt does not form hydrates. The heat of solution on dissolution of 1 mol of salt in 400 mol of water is + 9.92 kJ at 18 °C, the integral heat of solution is + 6.57 kJ/mol at 30 °C, and the differential heat of solution for saturated solution is + 6.07 kJ/mol at 30 °C. Ammonium sulfate deliquesces only above 80 % relative humidity; therefore, the salt can be stored in dry air. The solubility of ammonium sulfate is reduced considerably by addition of ammonia: At 10 °C, from 73 g $(NH_4)_2SO_4$ in 100 g of water, nearly linearly, to 18 g salt in 100 g of 24.5 % aqueous ammonia.

Figure 11. The system $(NH_4)_2SO_4$–H_2O

Calcium sulfate is approximately twice as soluble in ammonium sulfate solution as in water, which favors reaction of gypsum or anhydrite with ammonium carbonate – ammonium sulfate solutions. The salt is insoluble in the usual organic solvents. Dissolution of ammonium sulfate in aqueous solutions of ethanol, propanol, butanol, acetone, pyridine, etc., causes two phases to form, one aqueous and the other the organic solvent.

Special Cr – Ni stainless steel is resistant to ammonium sulfate solutions and to solutions of the salt in sulfuric acid. Ammoniacal solutions do not attack iron or aluminum. If the solutions contain substances that corrode stainless steel (e.g., Cl^-), the vessels can be lined with acid-resistant bricks.

2.2. Production

Ammonium sulfate is produced from

1) Coke-oven gas
2) Ammonia and sulfuric acid
3) Organic syntheses, such as the production of caprolactam
4) Gypsum, ammonia, and carbon dioxide

2.2.1. From Coke-Oven Gas

The production of ammonium sulfate from coke-oven gas has diminished considerably over the past twenty years, because of the partial closure of steel mills and the development of coking processes producing less ammonium sulfate [46].

In the direct process the unpurified coke-oven gas is introduced into sulfuric acid to yield ammonium sulfate contaminated by colored tar products. In the indirect process the ammonia is washed out of the coke-oven gas with water, released with a lime suspension, and finally introduced into sulfuric acid.

2.2.2. From Ammonia and Sulfuric Acid

The heat of reaction between ammonia and sulfuric acid is sufficient to evaporate all the water if an acid concentration of 70 % or higher is used.

$$2\,NH_3\,(g) + H_2SO_4\,(l) \longrightarrow (NH_4)_2SO_4\,(s) \qquad \Delta H = -274\,\text{kJ/mol}$$

Today, the reaction is usually carried out in saturators, devices that are derived from the evaporation crystallizers commonly used earlier [47–49].

In the saturator process (Fig. 12), neutralization and crystallization are carried out in one and the same apparatus. The sulfuric acid is delivered to the suction side and the ammonia to the pressure side of the forced circulation pump. Crystallization of the metastable solution gives particle sizes generally between 0.5 and

3 mm. The salt is continuously discharged at the lower end of the saturator. The salt is separated in centrifuges, dried, and cooled. The mother liquor is returned to the saturator. Impurities in the sulfuric acid can adversely affect crystallization. Small quantities of phosphoric acid, urea, or inorganic salts are added to promote crystal growth.

Figure 12. Ammonium sulfate saturator
a) Centrifuge; b) Mother liquor tank

2.2.3. Coproduct in Organic Syntheses

Ammonium sulfate is coproduct in the production of synthetic-fiber intermediates, such as caprolactam, acrylonitrile, and methyl methacrylate, and in the production of formic acid and acrylamide. The most important source is the production of caprolactam, which is required for nylon 6. The conventional caprolactam process (→ Caprolactam) produces 2.5 – 4.5 t of ammonium sulfate per tonne of lactam. Of that, 0.3 – 2.8 t is formed in the hydroxylamine – oximation stage and approximately 1.7 t in the Beckmann rearrangement stage. Crystallizers are used in the evaporation of ammonium sulfate solutions that result from caprolactam production. The processes developed by BASF [50], [51], Inventa [50], [52], [53], Toray Industries [54], Snia Viscosa [50], Techni-Chem [52], Kanebo [54], [55], and DSM [56] have reduced the 2.5 – 4.5 t, in some cases, to 1.7 – 1.8 t per tonne of lactam.

2.2.4. From Gypsum

Both anhydrite and gypsum react with NH_3 and CO_2:

$$CaSO_4(\cdot 2\,H_2O) + (NH_4)_2CO_3 \longrightarrow (NH_4)_2SO_4 + CaCO_3(+2\,H_2O)$$

The process, developed by BASF during the First World War, has retained its importance where sulfuric acid is in short supply, including India, Pakistan, and Turkey.

Finely ground gypsum is reacted with ammonium carbonate solution in a cascade of stirred vessels. The residence time is several hours. The reaction mixture of calcium carbonate and ammonium sulfate solution is filtered on rotary vacuum filters. The washed calcium carbonate can be used for fertilizing lime, the production of calcium ammonium nitrate, raw material for glass, or filler for rubber or PVC [57]. The slightly cloudy ammonium sulfate solution is filtered in filter presses, acidified with H_2SO_4, and processed in multistage evaporation crystallizers to form coarse-grained ammonium sulfate. (For details and a flowsheet, see [58]) An alternate method for converting gypsum into ammonium sulfate and calcium carbonate is the Continental Engineering Process [59], in which NH_3 and CO_2 are directly introduced into a gypsum slurry in a tall, cylindrical stirred vessel.

In principle, byproduct gypsum from the phosphoric acid process may be used too. However, it may contain phosphoric acid, silicates, fluorosilicates, and organic substances, which make filtering difficult, and may require preliminary washing.

2.2.5. Other Processes

There are several obsolete processes that start from SO_2 and atmospheric oxygen [60], [61]. There has been interest in processes using am-

monia to remove SO_2 from power-station exhaust. For example, the Walther process [62] produces a concentrated ammonium sulfite solution by two-stage washing of the dust-free exhaust. The solution is oxidized with atmospheric oxygen and spray-dried to ammonium sulfate powder, which is subsequently granulated [63].

2.3. Granulation and Storage

Typical crystallizers generally produce a 0.5- to 3-mm grain that can be dried to a water content of less than 0.1 %. The free acid content should not exceed 0.03 %, and the N content should not be below 21 %. The grains are protected against caking, generally by small quantities (0.1 %) of surfactants, and are storable.

For use in bulk blending, a procedure for producing the blended fertilizers widely used in the United States, the ammonium sulfate is generally granulated. This is done by compacting, pan granulation, or use of the TVA Ammoniator-Granulator [64]. Granulation can be improved by the use of additives, e.g., calcium salt [65]. The mixed granulation of concentrated urea solutions with ammonium sulfate crystals, e.g., in a pan granulator, gives a hard granulate of high nitrogen content (30 – 43 % N) suitable for bulk blending [66].

2.4. Uses

Almost all of the ammonium sulfate (AS) produced is used as fertilizer; very little is used industrially. In industrial countries ammonium sulfate is almost always a coproduct or byproduct, and it can only be sold as a fertilizer, mostly in the developing countries (Table 5). In industrial countries its low nitrogen content makes transportation cost per unit of nitrogen higher than for other nitrogen fertilizers. In Africa and Asia ammonium sulfate is used especially to fertilize rice, tea, and rubber. In Europe, the United States, and Brazil, it is often a component in blended and complex fertilizers (→ Fertilizers).

In industry $(NH_4)_2SO_4$ is used for the production of persulfates, flameproofing agents, and fire-extinguishing powders; in tanning; in the photographic, textile, and glass industries; and as a nutrient for yeast and bacterial cultures.

2.5. Economic Aspects

World ammonium sulfate capacity is shown in Table 6 [46]. Table 7 [46] shows the worldwide consumption of ammonium sulfate, which stagnated in 1976. As can be seen from the tables, production capacities are by no means fully utilized.

The transportation costs for shipping ammonium sulfate from the countries in which it is produced, the industrialized countries, into the countries in which it is consumed, the developing countries, reduces any profit. Production in some countries, e.g., China, Mexico, and Spain, has been based on a political decision – to increase domestic employment or preserve limited foreign exchange. In addition, worldwide consumption has been decreasing steadily. These three facts have been the driving force in the industrialized countries behind reducing the coproduction of ammonium sulfate in the production of synthetic fibers. If efforts to reduce sulfur emissions produce additional amounts of ammonium sulfate, which also will have to be sold in the developing world, the pressure on profits will increase further.

3. Ammonium Chloride

Although ammonium chloride [*12125-02-9*], NH_4Cl, M_r 53.49, occurs naturally in volcanic material, production from natural sources is of no significance. The history of industrial NH_4Cl production is intertwined with the development of the soda industry and the large-scale production of synthetic NH_3. The original motivation for producing ammonium chloride was to use it as fertilizer, but it is now used for a wide range of purposes. Ammonium chloride processes are

Oceania	24.7	31.3	21.9	26.8	63.3

of historical interest to chemical engineering because they are an early example of chemical processing involving all three phases: solid, liquid, and gas.

3.1. Properties

Solid ammonium chloride has a specific gravity d_4^{20} of 1.530. Its average specific heat $\overline{c}_p$ between 298 and 372 K is 1.63 kJ/kg.

Ammonium chloride has two modifications [67]. The transformation between the two is reversible at 457.6 K (184.5 °C):

$$\alpha\text{-}NH_4Cl \text{ (cubic, CsCl type)} \leftrightharpoons$$
$$\beta\text{-}NH_4Cl \text{ (cubic, NaCl type)} \rightleftharpoons$$
$$\Delta H = +4.3 \text{ kJ/mol}$$

The α modification is the one stable at room temperature. β-NH_4Cl melts at 793.2 K under 3.45 MPa; it sublimes at atmospheric pressure. In fact, NH_4Cl is quite volatile at lower temperatures, dissociating into NH_3 and HCl:

T, K	523.2	543.2	563.2	583.2	603.2	611.2
p, kPa	6.6	13.0	24.7	45.5	81.4	101.3

The solubility of NH_4Cl in water increases with temperature

T, K	273.2	293.2	313.2	333.2	353.2	373.2	389.2
c, wt %	22.9	27.2	31.5	35.6	39.7	43.6	46.6

The integral heat of solution to saturation is + 15.7 kJ/mol, and the differential heat of solution at saturation is + 15.2 kJ/mol. The solubility in water may be increased by adding ammonia. NaCl tends to salt NH_4Cl out of aqueous ammoniacal solution [68], [69]. The partial pressures of saturated NH_4Cl solutions show that NH_4Cl is weakly hygroscopic

T, K	283.2	293.2	303.2	313.2	323.2	389.2
p, kPa	1.0	1.9	3.3	5.4	8.8	101.3

Moisture causes product caking; however, whether moisture contents less than 0.1 wt % alone are responsible for the caking of ammonium chloride, is questionable. Another possible explanation is sublimation.

Ammonium chloride is very soluble in liquid NH_3 but virtually insoluble in acetone and pyridine. At 292.7 K its solubility in methanol is 3.24 wt %, and its solubility in ethanol is 0.64 wt %.

The crystal form obtained from aqueous solutions can be affected by other substances. This was exploited to produce large crystals, and it is

a help in determining impurities arising during NH_4Cl production [70], [71].

3.2. Production

Ammonium chloride is produced commercially by two processes:

1) Modified Solvay process (ammonia – soda ash process or ASAP)
2) Direct reaction between HCl and NH_3

A third process, the reaction of reciprocal pairs of salts [72], has not yet been commercially applied, but is still of interest.

3.2.1. Modified Solvay (Ammonia – Soda Ash) Process

In the Solvay process, ammonia and carbon dioxide are dissolved in aqueous sodium chloride to produce sparingly soluble sodium bicarbonate, which is calcined to sodium carbonate. The ammonia is recovered from the mother liquor by reaction with lime, this reaction also producing the calcium chloride. The source of the lime and the carbon dioxide is limestone. The net reaction is the conversion of the feedstocks rock salt and limestone into sodium carbonate and the byproduct calcium chloride.

Water, carbon dioxide, and ammonia are added only to the extent necessary to compensate for plant losses. The feedstock and product dictate the location of a Solvay plant. For this reason, the plants normally function as largely independent units (→ Sodium Carbonates).

The modified Solvay process (ammonium chloride – soda ash process) is one of the oldest examples of integrated industrial production of two substances. It differs from the Solvay process in that ammonium chloride is also precipitated from the mother liquor. The net reaction is

$$2\,NH_3 + CO_2 + H_2O + 2\,NaCl \longrightarrow 2\,NH_4Cl + Na_2CO_3$$

The amounts of ammonium chloride and soda ash produced are almost equal: two moles (107 g) of NH_4Cl are produced for each mole (106 g) of Na_2CO_3. The modified process, requiring external NH_3 and CO_2, must be incorporated into an integrated system of plants.

Furthermore, the treatment of ammonia-containing waste gases is carried out for environmental reasons, rather than to reduce NH_3 and CO_2 losses. Finally, the energy balance in the modified process is entirely different from that in the traditional Solvay process because of the different feedstocks and products.

Process Description. As a rule, the manufacture of NH_4Cl and Na_2CO_3 is carried out in a continuously operated recycle process in which the concentrations within the cycle may be adjusted according to whether ammonium chloride or sodium carbonate is the primary product [76]. BASF originally developed the process in which NH_4Cl is the primary product (Fig. 13).

The cycle begins with the addition of ammonia and carbon dioxide to the aqueous recycle solution. The ammonium bicarbonate intermediate reacts further with the sodium chloride present in the solution to yield ammonium chloride and sparingly soluble sodium bicarbonate. After thickening, the latter is separated out with a centrifuge; it is washed during centrifugation. It is calcined to produce sodium carbonate.

The sodium bicarbonate remaining in the mother liquor is decomposed by heating to 337.2 K. The very soluble sodium carbonate does not interfere with the crystallization of ammonium chloride. The high temperature of the solution at this point is utilized to dissolve the rock salt feedstock rapidly. This rock salt is introduced via a series of mixing tanks, the quantity dictated by the material balance over the entire cycle. Any insoluble impurities in the rock salt are filtered off. The major impurities are sulfates and other salts of iron, calcium, and magnesium. Disposal of the residues represent an increasing problem. Therefore, pure salt is replacing rock salt as raw material.

Ammonium chloride is recovered from the clear solution in a two-stage crystallization by indirect cooling. The suspension from the crystallizer is thickened in hydrocyclones, and the solid is separated and washed in a centrifuge. The solid from the centrifuge containing 5 – 7 wt % water is dried in a current drier to a moisture content less than 0.1 %. The final product can be coated with an anticaking agent. After the removal of the ammonium chloride, the cycle is complete, and the mother liquor can be reused.

Figure 13. Ammonium chloride – soda ash process

A process that produces soda ash as the primary product has been developed by Asahi Glass [77], [78].

Ammonia is added to the mother liquor prior to the crystallization of ammonium chloride. Crushed raw salt is added with or without washing and dissolved in the solution. The solution is then cooled below 20 °C to crystallize ammonium chloride. The crystals are separated with a centrifugal separator, and the mother liquor is recycled to the carbonation section. The ammonium chloride crystals are dried to a moisture content below 0.3 % in a rotary or fluidized bed drier. Crystal sizes can be kept between 1 and 2 mm for granule or about 200 µm in diameter for high-grade compound fertilizer.

In the carbonation section, the solution is sent into a carbonating tower for the precipitation of sodium bicarbonate through the reaction with blown-in carbon dioxide at 30 – 40 °C. The resulting slurry is separated into sodium bicarbonate crystals and the mother liquor. The mother liquor is sent to the ammonia absorption section. The separated crystals are calcined and converted to dense soda ash.

This process is capable of producing bicarbonate as pure as that from the conventional Solvay process and fertilizer-grade ammonium chloride. The purity of ammonium chloride exceeds 97 wt %.

As shown in Figure 14, the Asahi Glass process includes all the steps shown in Figure 13; however, the sequence differs. The ammonia is added after separation of the sodium bicarbonate. The heat of solution of ammonia serves to provide the heat needed to decompose the residual sodium bicarbonate. However, the energy saving is offset to some extent by the higher energy need in the crystallization because ammonium chloride is more soluble in the ammonia-rich solution [68], [69]. A washing step for the rock salt feed, prior to solution, avoids the filtration before crystallization. With or without washing this process utilizes the raw salt to the fullest extent, an important consideration in Japan where the salt must be imported.

Equipment Variations. Little is known about the process details of the individual process variants. Nevertheless, general characteristics of the process technology, adequate for plant selection, can be provided.

The individual steps of several other important process variants are described below.

If the feed gases are available at sufficiently high pressure, they can be mixed with the recycle solution by gas – liquid contacting devices, such as jet injectors. In the case of ammonia the amount of excess gas is reduced, and the solution is homogenized rapidly. In the case of CO_2 the nucleation rate and crystal growth of $NaHCO_3$ are improved.

Figure 14. Soda ash – ammonium chloride coproduction process

Further parameters influencing the size of the $NaHCO_3$ crystals are temperature and residence time in the carbonation step. The various carbonation columns used in the production of $NaHCO_3$ differ in the number and type of internal parts such as mixing devices and additional heat exchangers, the positioning and type of the CO_2 nozzles, and the volume needed to produce a given $NaHCO_3$ equivalent. The large $NaHCO_3$ crystals may be separated and washed using a band filter, or after thickening they may be separated by centrifugation.

The important differences in NH_4Cl crystallization lie in the number of stages and type of cooling. Direct cooling during the crystallization, in comparison with indirect cooling, uses more energy and requires the use of additional equipment for refrigerant condensation and recovery. However, it avoids problems associated with indirect cooling, i.e., the operation of heat exchangers, from which a NaCl crust must be periodically removed. Special plate heat exchangers have been developed to solve the fouling problem, and these are to be preferred to shell and tube heat exchangers and coil coolers.

$NaHCO_3$ and NH_4Cl crystallization and removal are the keys to high conversion per pass and product purity.

Ammonium chloride is frequently dried in a drum drier instead of a pneumatic drier.

Pollution Problems. The pollution problems associated with plant operation are not critical. By careful operation the production of wastewater streams can be almost entirely eliminated. However, because of its high ammonia content, any wastewater produced will require treatment.

The scrubbing of waste gases with hydrochloric acid to produce additional ammonium chloride offers a neat solution to the problem of gaseous emissions. Generally ammonia conversions of 98 % and rock salt conversions of 95 % are achieved, the exact values depending on the type of process and the environmental measures.

Grades and Capacity. After closure of several production plants due to reduced market demand, the capacity for NH_4Cl by the modified Solvay process for the western hemisphere and Japan was estimated at ca. 100000 t/a in 1997. Only limited information is available on total capacities and applied technology in China. In Asia, a granular product containing more than 97 % NH_4Cl is usually produced. The ammonia nitrogen content of this fertilizer grade NH_4Cl always exceeds 25 wt %. These plants are primarily for the production of soda ash.

However, if the production of NH_4Cl is of primary interest, the process can be carried out in such a way as to give purities exceeding 99.7 wt % NH_4Cl with < 0.25 wt % NaCl and < 3 ppm Fe, a quality adequate for most industrial purposes. Reagent-grade NH_4Cl can be produced on a large scale with special operat-

ing techniques but without additional processing steps. This ammonium chloride contains < 0.01 wt % NaCl and corresponds to the ACS specification [79].

3.2.2. Direct Reaction Between HCl and NH_3

The synthesis of NH_4Cl from HCl and NH_3 is economically attractive if HCl is available as feedstock at low or no cost.

The *Engeclor process* [80], developed by the Brazilian company Engeclor, carries out the reaction in aqueous solution:

Ammonia is fed into the conical section of a saturator while HCl diluted with air is passed into the NH_4Cl suspension. The reaction occurs at 353 K, under reduced pressure, and with excess NH_3 (pH 8). The suspension is drawn off from the base of the saturator and thickened in hydrocyclones. The NH_4Cl is separated in a centrifuge and dried. The mother liquor is recycled to the saturator. The waste gases from the saturator are scrubbed with water.

Schemes have been proposed whereby gaseous feedstocks are fed into nonaqueous solvents. The heat of reaction

$$NH_3(g) + HCl\ (g) \rightleftharpoons NH_4Cl\ (s)\ \Delta H = -176\ \text{kJ/mol}$$

is removed by the evaporation of the solvents, which are subsequently condensed [81]. Fluidized bed processes have also been described [82]. To avoid aerosol formation, carbon dioxide is recommended as carrier gas in the fluidized bed [102].

The annual world production of NH_4Cl via the $HCl - NH_3$ process was estimated to be 50000 t in 1997. Ammonium chloride produced by this method generally contains < 0.1 wt % NaCl. The metal content, and especially the heavy metal content, depends on the plant. As a rule the levels are higher than those encountered in the modified Solvay process.

3.2.3. Reaction of Reciprocal Pairs of Salts

The reaction of reciprocal salts [72] is still of interest. Suitable pairs of salts seem to be $(NH_4)_2SO_4 - KCl$, which gives $NH_4Cl - K_2SO_4$ [73–75][103][104] and $(NH_4)_2SO_4 - NaCl$ which gives $NH_4Cl - Na_2SO_4$ [106]. The basic problem with these salts is the lower purity of NH_4Cl due to the high content of sulfate. NH_4Cl and KNO_3 are obtained by reaction of NH_4NO_3 and KCl. Different process modifications are described in [105, 107–109]. High-purity KNO_3 can be used in manufacturing explosives, and NH_4Cl with a purity of 96 % min. can be used as a fertilizer. The preparation of $NaNO_3$ and NH_4Cl from NaCl and NH_4NO_3 has been investigated [110], [111].

3.3. Corrosion

Ammonium chloride is corrosive, as gas, as solid, or in solution, because (1) it is acidic, (2) it complexes metal ions, and (3) it contains the corrosive chloride ion. Therefore, corrosion protection is one of the key factors for production reliability and product quality. Several forms of corrosion are observed.

For solutions, the extent of corrosion largely depends on the NH_4Cl concentration, the pH, and the temperature. Equipment made from iron, aluminum, lead, or nonferrous metals is especially prone to stress corrosion cracking.

Older plants were constructed with rubber-lined pipes and containers that had an additional ceramic coating. Today special steels or plastics are usual. Low carbon, pure austenitic, or austenitic – ferritic steel, for example, that designated as SS 360 in the United States, is used up to 313 K. In borderline cases Hastelloy or Ti [83] is used.

The steel must be correctly worked. For example, welding must be carried out under a protective gas, and welded seams always should be posttreated. Up to 333 K polyethylene or fiberglass-reinforced polypropylene can be used where abrasion and erosion are absent. Heat exchangers of the graphite material Diabon have proved satisfactory. Cloths made from polyacrylonitrile are most suitable for filtration. Protection against external corrosion may also be necessary. Protective coatings with an epoxide or phenoxy resin base have proved effective. Such coatings are effective also for the internal protection of vessels or tanks not exposed to much mechanical wear and tear, such as storage silos.

3.4. Packaging, Storage, Shipping, and Handling

On account of its corrosive nature and its tendency to cake, NH_4Cl is best packed in sacks, or in the case of "flowable" goods in big bags, of paper or polyethylene rather than plastic or metal drums.

Despite its low water content (< 0.1 wt %) ammonium chloride tends to cake. There are two methods to enhance the "flowability." First, additives such as soda or B_2O_3 serve to separate the individual particles and preferentially absorb any water present. Product coated with such materials retains the ability to flow freely for a limited storage period and can be stored in silos on a temporary basis. Second, individual particles are encapsulated with hydrophobic chemicals. Fatty acid amines, e.g., stearylamine, and their acetate and hydrochloride derivatives are commonly used.

No special precautions beyond those usual for chemicals are needed for shipping ammonium chloride. Ammonium chloride should not be allowed to come into contact with nitrates or strong acids or alkalies. It is not covered by industrial chemical legislation although European Economic Community guidelines require labeling as a weak poison [84]. Ammonium chloride for the food industry must meet the specifications of the *European Pharmaceutical Handbook* [85] in Europe and those of the Food and Nutrition Board [86] in the United States. The latter restrict the use of anticaking agents.

3.5. Uses

Ammonium chloride is widely used as an effective nitrogen fertilizer for paddy and upland rice, wheat, and other crops in Japan, China, and South East Asia [77]. Most of the annual production of NH_4Cl in Japan is used as high-grade compound fertilizers: chloro-ammonium phosphate, chloro-potash-ammonium phosphate, magnesia-chloro-potash-ammonium phosphate, and nitrogen-potash. Further fertilizer uses are limited by the acidity and high chlorine content.

The industrial uses of technical-grade ammonium chloride are, in order of importance: solid electrolytes in dry cell batteries, one component of quarrying explosives (an especially fine form is used), hardeners for formaldehyde-based adhesives, one component of etching solutions in the manufacture of printed circuit boards, and a component, along with zinc chloride, of fluxes in tin and zinc plating. Minor uses include a rapid fixer additive in photography, cleaner additives, and a nutrient in yeast cultures. Ammonium chloride is also used in tanning, refining of precious metals, textile printing and dying, and in the rubber industry. The addition of ammonium chloride to tiles and bricks prior to firing was proposed. The ammonium chloride serves to control product porosity and accelerates the firing process [87]. The use of NH_4Cl as hardener for formaldehyde-based adhesives has been reduced significantly due to substitution by chloride-free products.

High-purity ammonium chloride is employed in the food and pharmaceutical industries and in a few chemical syntheses.

4. Ammonium Carbonates

Salt of hartshorn was first mentioned at the beginning of the 14th century in English manuscripts. It was produced by dry distillation of antlers, hooves, and leather and consisted of a solid mixture of NH_4HCO_3, $NH_4CO_2NH_2$, and $(NH_4)_2CO_3 \cdot H_2O$. This salt of hartshorn was used as an expanding agent for certain baked goods on account of its decomposition into entirely gaseous products and good handling properties. It was manufactured on a semi-industrial scale at the beginning of the 19th century.

Following the development of the industrial synthesis of ammonia, BASF started large-scale production of ammonium carbonate in 1919. Today, the term salt of hartshorn refers to a mixture of pure NH_4HCO_3 and $NH_4CO_2NH_2$ containing 32.5 wt % NH_3. The following compounds appear in the ternary system NH_3–CO_2–H_2O [88], [89]:

NH_4HCO_3	ammonium hydrogencarbonate
$(NH_4)_2CO_3 \cdot H_2O$	ammonium carbonate
$(NH_4)_2CO_3 \cdot 2\,NH_4HCO_3 \cdot H_2O$	ammonium sesquicarbonate
$NH_4CO_2NH_2$	ammonium carbamate

All these substances can be produced from NH_3 and CO_2. The high purity of the feedstocks

assures adequate product purity without further processing, provided the materials of construction are suitable.

4.1. Ammonium Hydrogencarbonate

Ammonium hydrogencarbonate [*1066-33-7*], ammonium bicarbonate, NH_4HCO_3, M_r 79.06, ϱ 1.586 g/cm^3. The decomposition pressure of ammonium bicarbonate increases rapidly with temperature [90]:

T, K	298.6	307.4	313.9	318.2	323.2	329.0	332.5
p, kPa	7.85	16.26	26.79	37.06	52.65	82.11	108.64

The solubility of ammonium bicarbonate in water increases with temperature [90]

T, K	273.2	283.2	293.2	303.2	313.2	323.2	333.2
c, wt %	10.6	13.9	17.8	22.1	26.8	31.6	37.2

The reaction forming NH_4HCO_3 is exothermic:

$$NH_3\,(g) + CO_2\,(g) + H_2O\,(l) \rightleftharpoons NH_4HCO_3\,(s) \qquad \Delta H = -126.5\,\text{kJ/mol}$$

In the $NH_3 - CO_2 - H_2O$ system, ammonium bicarbonate is the only compound soluble in water without decomposition. Upon dissolution of one mole of salt in 6 – 8 L H_2O the heat of solution is + 26.4 kJ at 288.2 K. The dissociation constant in aqueous solution is $K_d = 1.45$ [91] for the reaction $NH_4HCO_3 \rightleftharpoons NH_4^+ + HCO_3^-$.

Ammonium bicarbonate is best produced in aqueous solution, be it continuously or batch. The process is relatively easy to control. The crystallization is the critical stage. The heat of reaction must be removed, while the residence time, concentration, and temperature profile have to be controlled to yield large, easily separable crystals.

The flow diagram of a continuous process is shown in Figure 15. Ammonia is added to the mother liquor, which is kept cool, to achieve the desired NH_3 concentration of slightly above 10 wt %. Carbon dioxide is added and allowed to react in an absorption column. The resulting solution, which has been warmed by the reaction, is cooled indirectly in a crystallizer. The crystal suspension is withdrawn, thickened in hydrocyclones, and passed to a centrifuge, where the solid is separated. This solid is pneumatically dried, cooled, and conditioned. The mother liquor is recycled. If stainless steel equipment is used, the product meets the specifications of the *European Pharmaceutical Handbook* [92] and the *Food Chemical Codex* [93] without further purification.

The world production in 1997 was estimated at ca. 100000 t/a, almost half of which was produced in the western hemisphere and the remainder in Asia. The process variants of individual producers usually differ in the absorption/crystallization equipment, and this also results in different particle size distributions. The theory of CO_2 and NH_3 adsorption is discussed in [94], and crystallization with direct cooling is described in [95].

Figure 15. Production of ammonium bicarbonate
a) Gas absorption; b) Crystallization; c) Centrifugation; d) Thickening; e) Drying

4.2. Ammonium Carbamate

Ammonium carbamate [*1111-78-0*], $NH_4CO_2NH_2$, M_r 78.08, melts in a sealed tube at 425.2 K.

Figure 16. Production of ammonium carbamate
a) Crystallizer; b) Thickening; c) Centrifuge; d) Drying

The dissociation pressures show that the compound is quite volatile and thermally unstable [90].

T, K	283.19	288.10	291.10	294.41	298.10
p, kPa	38.0	55.3	68.50	88.50	114.80
T, K	299.97	304.10	309.07	313.05	318.02
p, kPa	130.40	173.70	242.70	315.30	431.00

The solid consists of dimers [96]. The heat of solution in water is + 15.9 kJ/mol.

Ammonium carbamate is manufactured by two methods. In the first process, which directly gives dry ammonium carbamate, predried NH_3 and CO_2 are fed into a heat exchanger, where they react and are cooled. The carbamate condenses within the pipes and is removed later by partial melting. This carbamate is sold as carbamate rocks.

The second process (Fig. 16), also semibatch, uses a concentrated $(NH_4)_2CO_3$ solution feed. Ammonia and carbon dioxide are fed into the solution, which is kept cool. The carbamate crystals are separated batchwise by centrifugation and dried pneumatically or under a protective CO_2 atmosphere.

A fluidized-bed process has been proposed for carbamate production [97].

Ignoring the large-scale production associated with urea manufacture (→ Urea), the world carbamate capacity in 1997 was estimated at 4000 t/a.

4.3. Ammonium Carbonate

Ammonium carbonate [*506-87-6*], $(NH_4)_2CO_3 \cdot H_2O$, M_r 114.11, crystallizes as flat, columnar, prismatic crystals or as elongated flakes. The carbonate melts at 316.2 K, simultaneously decomposing to the carbamate and sesquicar-

bonate. $(NH_4)_2CO_3 \cdot H_2O$ is only formed under precisely defined conditions, which are difficult to achieve in any production plant. Therefore usually equimolar mixtures of ammonium carbamate and ammonium hydrogencarbonate are used and sold as ammonium carbonate. These mixtures contain the same amount of ammonia as $(NH_4)_2CO_3 \cdot H_2O$. The world carbonate capacity in 1997 was estimated at 7000 t/a.

4.4. Storage, Transport, and Handling

The ammonium carbonates show noticeable dissociation pressures at temperatures as low as 293 K. Both carbamate and carbonate decompose to yield the bicarbonate, resulting in product losses and composition changes. For this reason the substances should be stored in sealed containers and kept as cool as possible. In sealed containers decomposition occurs only to a limited extent because progressive decomposition is prevented by the establishment of equilibrium. The rate of decomposition of NH_4HCO_3 is also a function of particle size [95]. Ammonium hydrogencarbonate has a tendency to cake, and its flowability is maintained by anticaking additives such as corn flour, saccharose, MgO, or $MgCO_3$.

There are, in general, no special requirements with regard to transport, safety precautions, and handling.

4.5. Uses

Ammonium bicarbonate is mainly used as an expanding agent for certain baked goods (→ Bread and Other Baked Products); it is also used in buffer solutions for neutralization of acids when additional anions are undesirable. Further uses include an ammonization agent for the humic acid in turf, a nitrogen source for yeast cultures, and blowing agents for foam rubber and poly(vinyl chloride). Minor uses include smelling salts and formaldehyde binders in laminates. Ammonium hydrogencarbonate is also used in the production of textiles, ceramics, pigments [98], and leather.

Ammonium carbamate is used as an insecticide for cereals, a neutralization agent in the chemical industry, and a feedstock for ammonium carbonate production.

Ammonium carbonate is used in the manufacture of catalysts [99–101], as blowing agent in foam rubber and foam plastic, and as an additive in photographic developers. In a number of countries it is also used as an expanding agent in certain baked goods.

5. Toxicology and Occupational Health

Ammonium chloride is harmful by ingestion; the oral LD_{50} in rats is 1410 mg/kg [112]. The i.v. LD_{50} in mice is 7 – 10 mmol/kg [113]. Ammonium chloride causes no skin irritation, but it is irritating to the eyes [114]. Ammonium chloride is not sensitizing in animals [115]. Oral treatment of various animal species with daily doses of 500 – 1000 mg/kg causes metabolic acidosis [116–118]: plasma and urinary pH and dioxide-combining power decrease, whereas chloride, urea nitrogen, and solids concentrations in the blood and gluconeogenesis increase. The Ames test [119][120] with *S. typhimurium* and *E. coli* and the micronucleus test [121] in mice did not show mutagenic effects. Ammonium chloride was not carcinogenic in rats and mice after chronic exposure in the diet and in drinking water [122–125].

Ammonium bicarbonate is harmful by ingestion. The LD_{50} (rat, oral) is ca. 1570 mg/kg [126] and the LD_{50} (mouse, i.v.) is 3.1 mmol/kg [127]. Rats fed for 8 days at a daily dose of 474 mg/kg showed only a slight increase in the ammonia content of the urine [128]. No mutagenic effects were detected in the Ames test with six different strains of *S. typhimurium* and in the chromosomal aberration test in vitro with a Chinese hamster fibroblast cell line [129].

Ammonium carbonate is virtually nontoxic after a single oral uptake. The LD_{50} (rat, oral) is 2150 mg/kg [126] and the LD_{50} (mouse, i.v.) is 1.02 mmol/kg [127]. Rats fed for 5 weeks with 5 % ammonium carbonate in the diet showed depressed growth and elevated urea concentrations in the blood [130]. Chinchilla rabbits were given 100 – 200 mg/kg ammonium carbonate by gavage or in their drinking water for 5 to 26 months [131], [132]. The treatment cycle was

for three weeks with the test compound followed by one week without. When ammonium carbonate was applied in the drinking water, the only notable effect was a parathyroid hypertrophy. Given by gavage ammonium carbonate leads to enlargement of adrenals, ovaries, mammary glands, and womb, as well as lactation and proliferation of ovarian follicles and corpora lutea. However, because these effects were found only in the gavage study, the relevance to humans seems to be doubtful.

Ammonium carbamate is harmful by ingestion. The LD_{50} (rat, oral) is in the range 690 – 1470 mg/kg [126] and the LD_{50} (mouse, i.v.) is 0.99 mmol/kg [127]. It is not irritating to rabbit skin, but irritates the rabbit eye [133]. No mutagenic effects were detected in the Ames test using four different strains of *S. typhimurium* [134]. Because ammonium carbamate is quite volatile and thermally unstable, forming ammonia and carbon dioxide, the MAK value of ammonia of 20 ppm (TWA 25 ppm) must be taken into account.

Analeptics

Alfred Hofmeister, Chemische Werke Minden GmbH, Minden/Westphalia, Federal Republic of Germany

Analeptics are pharmaceuticals for treatment of depressed excitability of the central nervous system. They comprise a varied group of substances, whose use in medicine is decreasing in importance continually. This fact can be explained by the increasing awareness that analeptics, as far as they are used as psychostimulants (e.g., amphetamines), frequently lead to abuse and drug dependence. Therefore, these drugs are controlled by narcotics laws, or they have been withdrawn completely from the market. However, this has not prevented their extensive use on the drug scene.

Analeptics have only one indication, namely, acute intoxication, such as hypnotic poisoning or postnarcotic complications with lesion of the respiratory and circulatory centers. For these cases, the following preparations are still available:

Bemegride [*64-65-3*], 4-ethyl-4-methyl-2,6-piperidinedione, $C_8H_{13}NO_2$, M_r 155.19, *mp* 127 °C. Trade names: Mikedimide (Panray), Eukraton (Nordmark), Malysol (Arco, Switzerland), Megimide (Nicholas). Bemegride is used in place of picrotoxin in acute poisoning with hypnotics.

Crotetamide [*6168-76-9*], *N*-(1-dimethylcarbamoylpropyl)-*N*-ethylcrotonamide, $C_{12}H_{22}N_2O_2$, M_r 226.31, *bp* 132 – 134 °C (30 Pa). Trade name (in combination with cropropamide [*633-47-6*]): Micoren (Ciba-Geigy).

Fominoben hydrochloride [*18053-31-1*], 3′-chloro-α-[methyl[(morpholinocarbonyl)-methyl]-amino]-*o*-benzotoluidide · HCl, $C_{21}H_{25}Cl_2N_3O_3$, M_r 438.36, *mp* 206 – 208 °C (decomp.). Trade name: Noleptan (Thomae), Oleptan (Bender, Austria), Terion (Lusofarmaco, Italy).

Amiphenazol hydrochloride [*490-55-1*], 5-phenyl-2,4-thiazole diamine · HCl, $C_9H_{10}ClN_3S$, M_r 259.78. Trade name: Daptazile (Nicholas).

Crotetamide, fominoben, and amiphenazol are used especially for treating acute respiratory disorders. Today the alkaloid lobelin [*90-69-7*] is seldom used.

Derivatives of amphetamine, which in fact are also analeptics, now are used only as appetite depressants, whereas derivatives of ephedrine are used mainly in combination drugs as bronchospasmolytics. The strongly psychostimulating drugs, such as *methamphetamine hydrochloride* [*537-46-2*], trade name Pervitin (Temmler), and *methylphenidate hydrochloride* [*113-45-1*], trade name Ritalin (Ciba), are considered correctly to be narcotics. *Pemolin* [*2152-34-3*], trade name Tradon (Beiersdorf), is still available as a mild stimulant.

The stimulating drugs used in psychiatry, for example, for depressions with retarded activity, are classified as psycho-active drugs, in particular, as the so-called thymoleptics. The antihypotonics used for treating low blood pressure are not classified as analeptics.

The methods available to modern intensive medicine have made the analeptics, which were much used previously, largely unnecessary. Attempts to deal with widespread misuse – by narcotics laws, obligatory prescriptions, and withdrawal of some preparations from the market – have been partially successful.

1. Introduction

Compounds that are used for the treatment of pain, inflammation, and fever are classified into two main groups according to their mode of action: nonsteroidal anti-inflammatory drugs (NSAIDs) and so-called centrally acting analgesics.

Nonsteroidal anti-inflammatory drugs are compounds with a predominantly peripheral mechanism of action. Besides inhibition of pain they exert a more or less pronounced anti-inflammatory and fever-reducing effect. In the body key peripheral mediators of pain, inflammation, and fever are prostaglandins (→ Prostaglandins). NSAIDs and related "peripheral" or "weak analgesics" act via inhibition of cyclooxygenase. Cyclooxygenase is the key enzyme of prostaglandin synthesis and its inhibition may be the most important, but not the exclusive mechanism of action of NSAIDs. The supposed additional mechanisms are widely unknown.

The group of *centrally acting analgesics* is dominated by the opioid compounds. They act mainly within the central nervous system, but more recent investigations indicate that an additional peripheral action component may exist. The endogenous opioid system is the most important pain control system within the body and opioids are powerful tools for the treatment of severe pain situations. Central neurotransmitters like noradrenaline and serotonin are likewise involved in pain inhibition. Directly acting compounds like, e.g., the α_2-adrenergic agonist clonidine as well as indirectly acting inhibitors of noradrenaline and serotonin reuptake (mainly used as antidepressants) have a definite value as primary analgesics or as co-analgesics in combination with opioids.

Acute pain is an alarm signal to alert the organism to noxious tissue damage, irritation, or injury. Ongoing, persistent or chronic pain may

© 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a02_269.pub2

lose this function and may become a mere burden to the patient. Pain does not only indicate physical suffering, but involves a strong mental and emotional component. According to the definition of the International Association for the Study of Pain "it is an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage".

The nervous system contains an afferent fiber system that is specialized for registration, transmission, and processing of nociceptive information. In the periphery small unmyelinated nerve endings, called nociceptors, are activated by mechanical, thermal, or chemical stimuli. One type, the mechano-heat nociceptor is specialized for thermal and mechanical stimulation, whereas the so-called polymodal receptor is less specific and responds to all kinds of mechanical, thermal, or chemical irritation. Mechano-heat nociceptors have a high stimulation threshold and respond only to strong stimuli. They are linked to small myelinated and rapidly conducting Aδ fibers which produce a sharp and well located pain sensation. The sharp pain stimulus activates withdrawal reflexes and has to protect the body against further damage. The polymodal receptors respond to weaker stimuli including endogenous compounds like histamine, bradykinin, and prostaglandins. These receptors are mediators of pain and inflammation and are released by tissue damage. The impulses of polymodal nociceptors are transmitted more slowly via thicker, unmyelinated C-fibers and provoke a dull, aching, and less precisely localized pain sensation. The nerve fibers originating from nociceptors are named primary afferent fibers. They have their cell body in the dorsal root ganglia and project to the dorsal root of the spinal cord where they form synapses with fibers of the ascending spino-thalamic pathway. Most of the spino-thalamic pain fibers pass the thalamus and project to the limbic system and the cortex. The limbic system is responsible for the emotional component of pain whereas in the cortex realization and localization of the origin of pain takes place. The spino-thalamic fibers form connections with the formatio reticularis of the brain stem, inducing the various vegetative reactions associated with the pain perception such as sweating, palpitation, nausea, and blood pressure increase.

Inhibitory control of the pain process can take place in the periphery at the level of the nociceptors or the primary afferents. These are the regions where local anesthetics and NSAIDs act. Central pain inhibition can take place at the level of the spinal cord, the thalamus, cortex, and the limbic system. The pain transmission at the level of the spinal cord is under inhibitory control of descending fibers, which originate in different parts of brain stem, mid brain, and cortex. They contain opioid synapses as well as noradrenergic and serotoninergic synapses and represent the descending spinal pain inhibitory system. Inhibitory opioid synapses are not only found in the spinal cord but are strategically located along the whole pain pathway. Opioid receptors are found in the cortex, limbic system, and formatio reticularis and this explains why opioids not only inhibit pain perception but also reduce the emotional component of pain suffering and mitigate the vegetative pain symptoms.

According to the clinical situation, pain can be classified as acute and chronic pain. *Acute pain* is induced by trauma, tissue damage, or disease and has a well defined localization and time course. Acute pain normally responds well to NSAIDs and opioid analgesics. *Chronic pain* is more complex in nature and often contains an inflammatory component. The association with trauma and lesion can be lost and then pain no longer fulfills its alarming function. Chronic pain is often a heavy burden to the patient and induces physical, psychological, and social deterioration. Chronic pain treatment is an important medical challenge.

Physiologically, pain can be differentiated into nociceptive and neuropathic pain. Nociceptive pain results from activation of nociceptors by acute or chronic stimulation and is not associated with damage of nerves. Neuropathic or neurogenic pain in contrast is the result of damage or dysfunction of the peripheral nerves or of the central parts of the pain processing system. Examples of neuropathic pain of peripheral origin are deafferentiation pain (stump pain), diabetic neuropathy, post herpetic neuralgia, trigeminal neuralgia, and sympathetically maintained pain like the complex regional pain syndrome. Central neuropathic pain may result from lesions of the spinal cord or brain lesions following stroke. In chronic cancer pain, nociceptive pain is often associated with a neuropathic component in-

duced by neoplastic nerve infiltration or compression of the nerve by tumor growth.

Cancer pain is one of the most important forms of chronic severe pain and guidelines for the treatment of cancer pain were published by the WHO in 1986 (Fig. 1).

Figure 1. WHO-Guidelines for Cancer pain treatment ("WHO-Ladder")

Meanwhile these guidelines have become the standard not only for treatment of chronic malignant pain but also for benign chronic and acute pain. The WHO proposal is often described as "treatment by mouth, by the clock, and by the ladder". That means that for repeated application of analgesics the oral route should be used. The application interval should be regular and selection of compounds should follow the increase of potency and efficacy as indicated in the three-step analgesic ladder. The first step starts with the single use of a non-opioid analgesic. If pain control is insufficient, a weak opioid may be added. If this is not effective enough, the weak opioid should be replaced by a strong opioid and the non-opioid may be omitted. Each stage of the treatment may be supplemented by the use of co-analgesics and other pharmacological and non-pharmacological treatments to improve pain control and to reduce side effects.

2. Nonsteroidal Anti-inflammatory Drugs (NSAIDs, COX Inhibitors)

In 1899 acetylsalicylic acid, the first nonsteroidal anti-inflammatory drug was registered under the name aspirin. Acetylsalicylic acid is still the best-known nonsteroidal anti-inflammatory drug and is used in almost every household for the treatment of mild to moderate pain states and fever. In 1971, it was shown that the analgesic action of nonsteroidal anti-inflammatory drugs is due to the inhibition of the enzymatic production of prostaglandins. Cyclooxygenase (COX) is the key enzyme in the conversion of arachidonic acid derived from lipids of the cell membrane to prostaglandins and other eicosanoids (Fig. 2).

Figure 2. Simple scheme of the biosynthesis of prostaglandins (PG), thromboxanes (TX), and leukotrienes from arachidonic acid consequent to cell injury (modified after [6])

The eicosanoids are important mediators in pain and inflammation leading to hyperalgesia by sensitization of nerve fibers and fever. Furthermore they fulfill important roles in the protection of the gastric mucosa, in platelet aggregation, and maintenance of normal kidney function [11]. The diversity of physiological functions of the eicosanoids is reflected by a variety of different receptors. Five main receptor types have been described, designated DP, FP, IP, TP, and EP, which show the greatest apparent affinity for PGD, PGF, PGI_2, TXA_2, and PGE, respectively [12]. PGE_2, the eicosanoid which plays a key role in pain perception, exerts this and other functions via the four subtypes of the EP receptors, EP1 – 4.

COX exists in two different isoforms, COX-1 and COX-2, characterized by different expression patterns. Both forms are encoded by two genes which have been cloned and sequenced

[13–16]. The cloning of the two isoforms led to further characterization of the enzymes by means of a whole range of molecular biology tools from knock-out mice [17–19] to protein structures [20, 21].

COX-1 is constitutively expressed in many cells of the body and responsible mainly for the production of eicosanoids serving normal physiological functions. One important physiological role is the protection of the gastric mucosa. Pain relief by inhibition of COX-1 is therefore often accompanied with gastrointestinal side effects.

COX-2 expression is induced during inflammation and is thought to be responsible for the production of eicosanoids in inflammatory conditions related to fever and pain. Furthermore, COX-2 is expressed in the central nervous system and might play a direct role in central pain processing.

Many nonsteroidal anti-inflammatory drugs of different chemical structures have been introduced for the treatment of inflammatory and painful conditions. Many years of clinical experience with these drugs have shown that there is no induction of tolerance and dependence and no respiratory depression as seen with opioids. The major side effects of these compounds with COX-1 specificity or balanced COX-1 and COX-2 inhibition are damage of the gastric mucosa, prolongation of bleeding time, and renal failure. The discovery of the inducible isoform led to the identification of drugs that show a stronger inhibition of COX-2 compared to COX-1 (Table 1).

The characteristic differences in expression of the two COX isoforms suggest a potential for new drugs addressing inflammatory and painful conditions specifically via inhibition of COX-2. The analgesic and anti-inflammatory potential of selective COX-2 inhibitors should come without the well known gastrointestinal side effects of classical NSAIDs targeting COX-1 alone or in combination with COX-2.

The first generation of COX-2 inhibitors like meloxicam still shows inhibition of COX-1 in physiological concentrations and hence, still generates gastrointestinal side effects of COX-1 inhibition although to a lower degree. The second generation of COX-2 inhibitors reached the market in 1999 with celecoxib and rofecoxib and shows a more than 100-fold selectivity for COX-2 compared to COX-1 (see also → Prostaglandins, Chap. 3). As expected, the gastrointestinal side effects of these drugs were shown to be clearly lower than those of classical nonsteroidal anti-inflammatory drugs like naproxen.

The ongoing research on the COX isoforms revealed that the strict differentiation of COX-1 as the constitutive enzyme and source of physiological (good) prostaglandins and COX-2 as the inflammation- and pain-mediated induced form of the enzyme, producing the "bad" prostaglandins is no longer valid. It was shown that COX-1 expression is also subject to regulatory processes and can be increased in inflammatory conditions [25]. COX-2 expression on the other hand is increased in the gastric mucosa by inflammatory stimuli and Helicobacter pylori infection [26, 27]. Finally, analysis of COX-1 and COX-2 knock-out mice indicated that both isoforms can contribute to an inflammatory response and have significant roles in the maintenance of physiological homeostasis and carcinogenesis [28]. These data suggest a more complex situation than the initial idea on the roles of COX-1 in normal and of COX-2 in inflammatory conditions, respectively.

Nevertheless, the COX-2 inhibitors showed a clearly improved gastrointestinal side effect profile and up to the year 2000 the newly developed coxibs seemed to displace the classical COX-1 selective NSAIDs from the market. The situation totally changed when the results of ongoing clinical studies and case reports revealed that COX-2 inhibitors seem to increase the risk of adverse thromboembolic events. The case reports came from patients with connective tissue diseases who developed arterial thrombosis after starting celecoxib treatment [29]. An increased number of cardiovascular events as compared to naproxen were seen in a large-scale randomized controlled trial [30], which investigated the efficacy and tolerability of rofecoxib (the VIGOR trial).

The concern about the risk associated with the COX-2 inhibitors increased rapidly and in September 2004 rofecoxib was withdrawn from the market because a trial, designed to test the hypothesis that COX-2 inhibitors would prevent recurrent colonic polyps, indicated an increased cardiovascular toxicity [31]. A similar trial with celecoxib, performed at the National Cancer Institute was stopped when an indepen-

Table 1. COX-2 specific inhibitors

Group	Compound	COX-2 selectivity	Reference
First generation		(< 100-fold)	
	etodolac	10	[22]
	meloxicam	10	[22, 23]
	nimesulide	5 – 100	[22, 23]
Second generation		(100 – 1000-fold)	
	celecoxib	375	[24]
	rofecoxib	800	[561]

dent panel of cardiovascular experts reviewed the data and also found a greater incidence of cardiovascular events among patients treated with celecoxib [32]. Negative data on cardiovascular tolerability were also seen with valdecoxib and its intravenous prodrug, parecoxib, given for pain treatment to patients recovering from coronary-artery bypass surgery [33]. In the beginning, the mechanism of the cardiovascular toxicity of the COX-2 inhibitors was unclear, but it emerged that it was a group effect of the coxibs and the most likely mechanism is a reduced production of the antithrombotic eicosanoid prostacyclin without changing the production of the prothrombotic compound thromboxane [34].

Besides the cardiovascular intolerability, the COX-2 inhibitor valdecoxib showed an increased risk of serious and potentially fatal skin reactions which was the reason for the suspension of marketing autorization. The remaining COX-2 inhibitors, etoricoxib and lumiracoxib, although having in principle a similar cardiovascular and skin tolerability risk, seem to be better tolerated and are still on the market, but doctors are advised to use COX-2 inhibitors only after careful consideration, and to treat their patients with the shortest course and the lowest possible dose of these compounds.

The unexpected tolerability problems with the COX-2 inhibitors have strongly reduced the enthusiasm originally evoked by these compounds and have re-established the therapeutic reputation of the COX-1 inhibitors and of compounds with a balanced COX-1 and COX-2 inhibition, although the gastrointestinal side effects remain a serious problem. Therefore there is increased need for new anti-inflammatory principles with better gastrointestinal tolerability and research activities have been focussed on new compounds combining COX-inhibition with other analgesic and anti-inflammatory principles such as inhibition of 5-lipoxygenase (5-LO) or release of nitric oxide (NO).

Dual COX and 5-LO Inhibitors. This new class of compounds is reported to have COX-2 and 5-lipoxygenase inhibiting properties [35]. The compounds were effective in several animal models of arthritis and were devoid of ulcerogenic properties. One of these compounds, S-2474, ((E)-5-(3,5-di-tert-butyl-4-hydroxybenzylidene)-2-ethyl-1,2-isothiazolidine-1,1-dioxide), which has a γ-sultam skeleton, additionally inhibits the production of interleukin-2 (IL-2) in in vitro assays. S-2474 was selected as development candidate and is now under clinical investigation [36].

ML-3000 ((2,2-dimethyl-6-(4-chlorophenyl)-7-phenyl-2,3-dihydro-1H-pyrrolizine-5-yl)-acetic acid) is a nonoxidant dual cyclooxygenase and 5-lipoxygenase inhibitor and has been compared with indometacin in a number of experimental models of inflammation and pain [37]. Corresponding to animal data the compound showed a wide range of activities in Phase II clinical studies, including anti-inflammatory, analgesic, antiplatelet and antiasthmatic properties [38, 39].

NO Releasing COX Inhibitors. Nitric oxide (NO) releasing non-steroidal anti-inflammatory drugs are a new and promising goup of analgesic and anti-inflammatory compounds. NO release is found as a mechanistically not yet resolved property of a few new COX-1 inhibitors such as amtolmetin [40] or it can be induced by adding a NO releasing moiety (e.g., nitroxybutyl) to existing COX-inhibitors [41]. The most advanced compounds are NO-naproxen and NO-flurbiprofen (NCX-2216).

Preclinical and clinical studies confirm that both NO-release and COX-1 or COX-2 inhibi-

tion take place in vivo, causing less adverse effects on the gastrointestinal tract than conventional NSAIDs and coxibs. In addition, the compounds reduce systemic blood pressure. Possible indications for NO-flurbiprofen are, besides pain inhibition and anti-inflammation, urinary incontinence, Alzheimer's disease, osteoporosis and Paget's disease [42]. A topical formulation is under development for the treatment of dermatological disorders such as contact urticaria.

A further group of NO-donating drugs (e.g., NCX-4016) has been obtained by coupling NO to aspirin. These compounds retain the analgesic, anti-inflammatory and antithrombotic properties of aspirin but show an increased gastrointestinal tolerability [43]. Animal studies have shown that NO-aspirins and the NO-donating NSAIDs maintain gastric mucosal blood flow and reduce leucocyte-endothelial cell adherence.

Up to 2006, no NO-COX inhibitor compound has yet reached the market.

Aspirin as an Antithrombotic Drug. Aspirin, the archetype of the COX inhibitors, is still one of the most interesting compounds of this group and has reached additional importance in the last decades due to its inhibition of platelet aggregation. It is used in low dose [44] in the treatment of acute and the prevention of chronic myocardial infarction and stroke (→ Cardiovascular Drugs).

Classification of COX Inhibitors. COX inhibitors, as it is done here, can be classified according to their chemical structure.

Classification According to Inhibition Specificity. A more functional classification is related to the specificity for inhibition of the COX-1 or COX-2 isoforms of the enzyme. The inhibition of the COX isoenzyme is strongly dependent on the test system used. Inhibition of COX can be quantified in recombinant or natural enzyme preparations, cellular systems, isolated human cell populations, such as platelets (COX-1) and white blood cells (COX-2), or in ex vivo stimulated whole blood samples. The more physiological the situation is, the smaller is the selectivity of most of the COX-2 selective inhibitors. The standard test for comparison is considered to be a whole blood assay which mimics in vivo conditions like plasma binding [45]. It is commonly accepted that reasonable variations in COX inhibition is found in different laboratories. Therefore, whenever possible, data of several compounds, generated within the same test situation, should be compared to each other.

Using this classification based on isoenzyme selectivity, there is besides low-dose aspirin no COX-1 selective inhibitor on the market. Instead, most of the classical NSAIDs belong to the group of nonselective COX inhibitors.

- *Selective COX-1 inhibitors* (low-dose aspirin)
- *Nonselective COX inhibitors* (e.g., high-dose aspirin, indometacin, and other NSAIDs)
- *Preferential COX-2 inhibitors* (e.g., meloxicam)
- *Highly selective COX-2 inhibitors* (e.g., celecoxib and other second- and third-generation COX-2 inhibitors, now called coxibs)

Classification According to Drug – Protein Interactions. Another classification is based on the mode of interaction between the inhibitor drug and the enzyme [46].

- *Irreversible inhibitors of COX-1 (aspirin) and COX-2 (APHS).* Aspirin and APHS [47] acetylate the amino acid serine in the catalytic center of the enzyme to a stable ester derivative so that the endogenic arachidonic acid is prevented from interaction with the enzyme.
- *Reversible, competitive inhibitors of COX-1 and COX-2.* Inhibitors such as ibuprofen, piroxicam, or mefenamic acid block the enzyme by competing with arachidonic acid for binding at the catalytic center.
- *Slow, time-dependent, reversible inhibitors of COX-1 and COX-2.* Compounds such as indometacin and flurbiprofen act by ionic interaction between the acidic carboxyl group of the inhibitor and the basic arginine residue of the enzyme. This seems to influence the helix D of the protein followed by a significant loss of flexibility of the enzyme protein.
- *Slow, time-dependent, irreversible inhibitors of COX-2.* The coxibs such as celecoxib, rofecoxib and lumiracoxib induce a strong, time-dependent inhibition of COX-2, but show only a minor competitive inhibition of COX-

1, which is of no relevance compared to the COX-2 inhibition.

COX Inhibitors in Clinical Use

2.1. Salicylates

Acetylsalicylic acid [*50-78-2*], aspirin, 2-acetoxybenzoic acid, $C_9H_8O_4$, M_r 180.04, *mp* 135 °C (for properties and synthesis, see → Salicylic Acid).

Synthesis [48, 49]:

Acetylsalicylic acid

Clinical use: Acetylsalicylic acid is the prototype of a nonsteroidal anti-inflammatory drug and is used in a large number of inflammatory and pain indications including musculoskeletal, soft-tissue and joint disorders, headache, dysmenorrhoea, and fever [50]. In addition acetylsalicylic acid is used as an antiplatelet drug for the prevention of myocardial infarction and stroke [44] and in combination with thrombolytics in the acute treatment of myocardial infarction.

Depending on the assay system, acetylsalicylic acid shows a balanced inhibition of COX-1 and COX-2 [23] or a selectivity towards COX-1 [22]. In addition to COX inhibition acetylsalicylic acid modulates the activities of several cellular kinases [51], which may contribute to its anti-inflammatory effects.

The inhibition of COX-1 and COX-2 by acetylsalicylic acid does not follow a competitive mechanism like with other nonsteroidal anti-inflammatory drugs but rather is due to a covalent enzyme inhibition via acetylation. After absorption, acetylsalicylic acid is hydrolyzed to salicylate which itself still shows some COX inhibition activity. Both compounds are bound to plasma proteins to 80–90 %. The plasma elimination half-life is about 15 min for acetylsalicylic acid and between 3 and 22 h for salicylate, depending on the dose [52]. Acetylsalicylic acid is usually administered orally (0.5–8 g/d) for pain and inflammation and for antiplatelet therapy (75–100 mg/d). It is also available in rectal and topical formulations and as soluble lysine derivative for intravenous or intramuscular application. Acetylsalicylic acid is often used in multi-drug preparations. The main side effects are gastrointestinal disorders. The use in children is limited due to the risk of Reye's syndrome [53]. The lithium, magnesium, calcium, and aluminum salts of acetylsalicylic acid are used in some special preparations.

Trade names: Aspirine (France), Aspirin, Aspisol (Germany), Aspro (UK), Alka Seltzer (USA).

Diflunisal [*22494-42-4*], 2′4′-difluoro-4-hydroxybiphenyl-3-carboxylic acid, $C_{13}H_8F_2O_3$, M_r 250.20, *mp* 210–211 °C (also reported as 212–213 °C).

Synthesis [48, 54–58, 505]: The diazotation of 2,4-difluoroaniline with isoamyl nitrite and condensation with anisole gives 4-(2,4-difluorophenyl)anisole, which is hydrolyzed with HI in refluxing acetic acid yielding 4-(2,4-difluorophenyl)phenol. Finally this compound is carboxylated with K_2CO_3 and CO_2 at 175 °C and 90 bar, followed by an acidification.

Diflunisal

Clinical use: Diflunisal [60] is a nonsteroidal anti-inflammatory drug used in the treatment of mild to moderate pain including osteoarthritis, rheumatoid arthritis, and primary dysmenorrhoea. It is used as base or lysine- or arginine-salt for oral or parenteral application.

Diflunisal is a weak inhibitor of both COX-1 and COX-2 [61].

Peak plasma concentrations are reached within 2 to 3 h after oral dosing. Diflunisal is strongly bound to plasma protein (> 99 %), has a long elimination half-life (8–12 h) and nonlinear elimination kinetics. Hence, it is used with an initial loading dose (1000 mg) and a lower maintenance dose (500–1000 mg/d).

The main side effects are gastrointestinal disturbances, headache and rash.

Trade names: Dolobis (France), Dolobid (Italy, UK, USA).

Ethenzamide [*938-73-8*], 2-ethoxybenzamide, $C_9H_{11}NO_2$, M_r 165.19, *mp* 132–134 °C.

Synthesis: Salicylamide is ethylated with diethyl sulfate [48, 62].

Clinical use: Ethenzamide is a nonsteroidal anti-inflammatory drug used mainly in combination with other ingredients for the treatment of mild to moderate pain including musculoskeletal and joint disorders.

Trade names: Trancalgyl (France).

Salicylamide [*65-45-2*], 2-hydroxybenzamide, $C_7H_7NO_2$, M_r 137.14, *mp* 140 °C.

Synthesis [48, 63]:

Clinical use: Salicylamide shows analgesic and antipyretic efficacy and was used in multidrug combinations for the treatment of a variety of mild pain conditions including musculoskeletal, soft-tissue, and joint disorders. It is now mostly substituted by newer COX inhibitors.

Trade names: Percutalgine (France), Intralgin (UK), Anabar (USA).

2.2. para-Aminophenol Derivatives

Paracetamol [*103-90-2*], acetaminophen, *N*-(4-hydroxyphenyl)acetamide, $C_8H_9NO_2$, M_r 151.16, *mp* 168–169 °C.

Synthesis:

a) classical route [48, 64]:

b) Hoechst-Celanese process:

Clinical use [65]: Paracetamol has analgesic and antipyretic properties, but no relevant anti-inflammatory action. It is used for the treatment of various mild to moderate pain conditions and to reduce fever. Despite a long therapeutic use, the mechanism of action of paracetamol is unclear. The compound shows some weak inhibition of COX-1 and COX-2,

and there are speculations that a third COX isoenzyme, named COX-3, may be inhibited [66]. Recently, a new and unexpected mechanism through which paracetamol could exert its analgesic effect was detected [67, 68]. Following deacetylation to its metabolite p-aminophenol, paracetamol is conjugated with arachidonic acid to give a compound named AM404. The metabolite AM404 affects several important targets in the nervous system involved in pain. AM404 inhibits purified COX-1 and COX-2 and prostaglandin formation in lipopolysaccharide-stimulated macrophages. AM404 is also a potent activator of the ion channel $TRPV_1$ (transient receptor potential cation channel, former classified as the vanilloid receptor VR_1) and has an effect on cannabinoid CB_1 receptors. Both $TRPV_1$ and CB_1 receptors are involved in pain and in thermoregulatory pathways.

Paracetamol is one of the most popular analgesics as single drug or in multi-ingredient preparations, often in combination with NSAIDs or weak opioids. It is used orally or rectally as suppositories, the oral dose range is 500–1000 mg every 4–5 h up to 4 g daily. Side effects are rare and may include hematological reactions, leucopenia, agranulocytosis and other hypersensitivity reactions. Paracetamol has a narrow therapeutic dose range and overdosage induces severe liver and renal damage [69] via accumulation of a toxic metabolite, *N*-acetylbenzoquinoneimine (NABQI). Acetylcysteine or methionine, which increase glutathione conjugation of the metabolite, are used as antidote.

Paracetamol is not soluble in aqueous solutions and cannot be given parenterally. A soluble glycine prodrug derivative has been developed for parenteral use (propacetamol, see below).

Trade names: Benuron (Germany, Switzerland), Dafalgan (France) Tylenol (Austria, Canada, USA, Spain), Alvedon (Norway, Sweden, UK).

Combination with codeine: Co-Tylenol (USA).

Combination with tramadol: Zaldiar (Germany, Austria, France, Spain, Switzerland), Tramacet (UK), Ultracet (USA).

Paracetamol is also used in many generic formulations.

Propacetamol [*66532-85-2*], 4-(acetylamino)phenyl *N*,*N*-diethylglycinate, $C_{14}H_2ON_2O_3$, M_r 264.33, is a soluble glycine prodrug derivative of paracetamol. It is used as hydrochloride ([*66532-86-3*], $C_{14}H_2ON_2O_3 \cdot HCl$, M_r 300.79), for intramuscular or intravenous application and is rapidly metabolized to free paracetamol [70].

Trade name: Pro-Dafalgan (Belgium, France), Pro-Efferalgan (Italy)

Phenidine [*62-44-2*], phenacetin, *N*-(4-ethoxyphenyl)acetamide, $C_{10}H_{13}NO_2$, M_r 179.22, *mp* 134–135 °C.

Synthesis [48]:

Clinical use: Phenidine is a weak analgesic, antipyretic compound without anti-inflammatory action. It has been used in combination with other compounds like aspirin, caffeine, or codeine, but due to hematological and nephrotoxic side effects [71] has been withdrawn from the market and substituted by the less toxic paracetamol.

2.3. Anthranilates

Etofenamate [*30544-47-9*], 2-(2-hydroxyethoxy)ethyl 2-(3-trifluoromethylphenylamino) benzoate, $C_{18}H_{18}F_3NO_4$, M_r 369.34, pale yellow viscous oil, thermolabile at 180 °C, *bp* (133.32 Pa) 130–135 °C.

Synthesis: Esterification of the potassium salt of flufenamic acid (see page 10) with 2-(2-chloroethoxy)ethanol in dimethyl formamide as solvent yields etofenamate [48, 72].

Etofenamate

Clinical use: Etofenamate [73] is a nonsteroidal anti-inflammatory drug which was used mainly as a topical formulation (500–1300 mg/d) and by intramuscular injection (1 g/d) for the treatment of joint, musculoskeletal and soft-tissue disorders.

Flufenamic acid [*530-78-9*], flufenamate, 2-[3-(trifluoromethyl)phenyl]aminobenzoic acid, $C_{14}H_{10}F_3NO_2$, M_r 281.23, *mp* 124-125 °C (also reported as 134-136 °C); aluminum salt (3 : 1) [*16449-54-0*], $C_{42}H_{27}AlF_9N_3O_6$, M_r 867.66.

Synthesis: 2-Chlorobenzoic acid is reacted with 3-trifluoromethylaniline in the presence of copper and potassium carbonate [48, 74, 75].

Flufenamic acid

Clinical use: Flufenamate is a nonsteroidal anti-inflammatory drug used for the treatment of mild to moderate pain of musculoskeletal, joint or soft-tissue origin. It was marketed in a variety of topical formulations alone or in combination with other ingredients.

Flufenamate is not recommended in patients with acute porphyria and was associated with acute proctocolitis [76].

In addition to COX inhibition flufenamate like other fenamates modifies several ion channel functions, e.g., inhibition of nonselective cation conductance [77], calcium-activated chloride channels [78], voltage-gated calcium channels and potassium channels [79, 80] and induces blocking of gap junctions [81]. The relevance of these activities for the analgesic and anti-inflammatory potential of fenamates is unknown.

Meclofenamic acid [*644-62-2*], meclofenamate, 2-[(2,6-dichloro-3-methylphenyl)amino]benzoic acid, $C_{14}H_{11}Cl_2NO_2$, M_r 296.15, *mp* 257–259 °C; monosodium salt monohydrate [*6385-02-0*], $C_{14}H_{10}Cl_2NNaO_2 \cdot H_2O$, M_r 336.15, *mp* 289–291 °C.

Synthesis: Meclofenamic acid is obtained by condensation of 2-bromobenzoic acid with 2,6-dichloro-3-methylaniline using $CuBr_2$ in diethyleneglycol dimethyl ether containing *N*-ethylmorpholine, and heating at 145–155 °C [48, 82–84] .

Meclofenamic acid

Clinical use: Meclofenamate [85] is a non-steroidal anti-inflammatory drug used for the treatment of mild to moderate pain, musculoskeletal, and joint disorders like rheumatoid arthritis and osteoarthritis as well as dysmenorrhoea. Meclofenamate inhibits COX-1 and COX-2 and modifies ion channels [86, 87] (see page 10).

Meclofenamate is administered orally (300–400 mg/d).

Trade names: Lenidolor (Italy), Meclomen (Austria, Spain, Switzerland, USA).

Mefenamic acid [*61-68-7*], 2-[(2,3-dimethylphenyl)amino]benzoic acid, $C_{15}H_{15}NO_2$, M_r 241.29, *mp* 230–231 °C; monosodium salt $C_{15}H_{14}NNaO_2$, M_r 263.27.

Synthesis [48, 88]:

Mefenamic acid

Clinical use: Mefenamic acid is a non-steroidal anti-inflammatory drug which is used for the treatment of mild to moderate pain conditions, musculoskeletal and joint disorders like rheumatoid arthritis and osteoarthritis, and dysmenorrhoea. [89]. Mefenamic acid inhibits both COX isoforms with some preference for COX-2 and modifies ion channels [90] (see page 10).

Mefenamic acid is given orally (1500 mg/d maximal dose). The main side effects concern the gastrointestinal system and include diarrhea [91].

Trade names: Ponstyl (France), Ponstan (UK), Ponstel (USA).

Niflumic acid [*4394-00-7*], 2-(3-trifluoromethylphenylamino)nicotinic acid, 2-[[3-(trifluoromethyl)phenyl]amino]-3-pyridinecarboxylic acid, $C_{13}H_9F_3N_2O_2$, M_r 282.22, *mp* 204 °C.

Synthesis: Condensation of 2-chloronicotinic acid with 3-trifluoromethylaniline or reaction of 2-aminonicotinic acid with 1-bromo-3-trifluoromethylbenzene yields niflumic acid [48, 92].

Niflumic acid

Clinical use: Niflumic acid [93] is a non-steroidal anti-inflammatory drug used for the treatment of inflammation and pain in musculoskeletal and joint disorders like rheumatoid arthritis as well as traumatic and postoperative pain. Niflumic acid is used in oral, rectal, or topical applications (up to 750 mg/d).

The morpholinoethyl ester morniflumate, which is used in topical formulations, inhibits both cyclooxygenase and 5-lipoxygenase which suggests an additional component of anti-inflammatory activity [94].

Trade names: Niflurid, Niflugel (Belgium, France, Switzerland), Actol (Austria, Sweden).

Tolfenamic acid [*13710-19-5*], 2-[(3-Chloro-2-methylphenyl)amino]benzoic acid, *N*-(3-chloro-*o*-tolyl)anthranilic acid; *N*-(2-methyl-3-chlorophenyl)anthranilic acid, $C_{14}H_{12}ClNO_2$, M_r 261.70, *mp* 207.0–207.5 °C.

Synthesis: Tolfenamic acid is obtained by condensation of 2-chlorobenzoic acid with 3-chloro-2-methyl-phenylamine using $CuBr_2$ in diethylenglycol dimethyl ether [95, 96].

Tolfenamic acid

Clinical use: Tolfenamic acid is a non-steroidal anti-inflammatory drug [97] used for the treatment of rheumatoid arthritis [98], osteoarthritis, ankylosing spondylitis, trauma pain, and dysmenorrhoea [99]. It is also used for the prophylactic and acute treatment of migraine [100]. The compound is further marketed for veterinary use.

Trade name: Clotam (Denmark).

2.4. Arylacetic Acids

Acemetacin [*53164-05-9*], carboxymethyl [1-(4-chlorobenzoyl)-5-methoxy-2-methyl-1*H*-indol-3-yl]-acetate, $C_{21}H_{18}ClNO_6$, M_r 415.82, *mp* 150–153 °C (fine pale yellow crystals).

Synthesis [48, 101] (see on top, right column).

In addition, the reaction product of indomethacin (see page 14) with benzyl bromoacetate can be hydrogenated to acemetacin.

Clinical use: Acemetacin [102] is a non-steroidal anti-inflammatory drug acting directly and via its major metabolite indomethacin. Acemetacin is used in chronic joint pain as well as in postoperative pain. Oral dosing is recommended between 120 and 360 mg daily.

Trade names: Rantudil (Germany), Emflex (UK).

Acemetacin is also used in several generic formulations.

Acemetacin

Proglumetacin [*57132-53-3*], 1-(4-Chlorobenzoyl)-5-methoxy-2-methyl-1*H*-indole-3-acetic acid 2-[4-[3[4-(benzoylamino)-5-(dipropylamino)-1,5-dioxopentyl]oxy]propyl]-1-piperanzinyl]ethyl ester, *rac-N*-[2-[1-(*p*-chlorobenzoyl)-5-methoxy-2-methyl-3-indolylacetoxy]ethyl]-*N′*-[3-(*N*-benzoyl-*N′*,*N′*-di-*n*-propyl-DL-isoglutaminoyl)oxypropyl]piperazine, $C_{46}H_{58}ClN_5O_8$, *Mr* 844.43, dimaleate, 4-Benzamido-5-(dipropylamino)-5-oxopentanoic acid 3-[4-[2-[2-[1-(chlorobenzoyl)-5-methoxy-2-methyl-1 *H*-indol-3-yl]acetoxy]ethyl]piperazin-1-yl]propyl ester dimaleate [*59209-40-4*], $C_{46}H_{58}ClN_5O_8$ $2C_4H_4O_4$, M_r 1076.58, *mp* 146–148°C.

Synthesis: The reaction of *N*-benzoyl-*N′*, *N′*-di-*n*-propyl-DL-isoglutamin (proglumide)

with 1-(3-chloropropyl)-4-(2-hydroxyethyl)-piperazine obtained from 1-(2-hydroxyethyl)piperazine and 1-bromo-3-chloropropane by means of sodium methanolate in DMSO at 105°C gives *N*-[3-(*N*-benzoyl-*N′*, *N′*-di-*n*-propyl-DL-isoglutaminyl)oxypropyl]-*N′*-(2-hydroxyethyl)piperazine, which is then condensated with Indomethacin (1-(*p*-chlorobenzoyl)-5-methoxy-2-methylindole-3-acetic acid) by means of dicyclohexylcabodiimide and $NaHCO_3$ in ethyl acetate [103, 104] (see on top).

Proglumetacine is a prodrug of acemetacine [105] and is used for the treatment of osteoarthritis, rheumatoid arthritis, gout, ankylosing spondylitis, and pain [106].

Trade names: Protaxon (Gemany), Proxil (Italy).

Bufexamac [*2438-72-4*], 2-(4-butoxyphenyl)-*N*-hydroxyacetamide, $C_{12}H_{17}NO_3$, M_r 223.12, *mp* 153–155 °C.

Synthesis [48, 107] (see right column).

Clinical use: Bufexamac is a nonsteroidal anti-inflammatory drug used in topical formulations for mild skin disorders and as suppositories (250–500 mg/d) for hemorrhoids.

Trade names: Duradermal (Germany), Parfenac (France, Germany).

Diclofenac [*15307-86-5*], [2-(2,6-dichlorophenylamino)phenyl]acetic acid, $C_{14}H_{11}Cl_2NO_2$, M_r 296.15, *mp* 156–158 °C; sodium salt [*15307-79-6*], $C_{14}H_{10}Cl_2NNaO_2$, M_r 318.13, *mp* 283–285 °C.

Synthesis [108]:

Clinical use: Diclofenac [109] is a nonsteroidal anti-inflammatory drug with balanced COX-1 and COX-2 inhibition [22]. It is commonly used for a variety of inflammatory and pain conditions such as musculoskeletal and joint disorders, periarticular disorders, soft-tissue disorders, renal colic, acute gout, dysmenorrhoea, and postoperative pain.

The plasma protein binding of diclofenac is greater than 99.5 % and the plasma elimination half-life is between 1 and 2 h.

Diclofenac is used mainly as the sodium salt orally or parenterally (75–150 mg/d) and as ophthalmic solution. Topical formulations may contain the diethylammonium or epolamine salt. Diclofenac is combined with misoprostol to reduce gastrointestinal side effects, which are the main adverse events and with weak opioids (codeine) to increase the analgesic potential.

Trade names: Allvoran (Germany), Diclac (Germany), Voltaren (Germany, Italy, USA), Voltarène (France), Voltarol (UK).

Combination with misoprostol: Arthotec (Germany).

Combination with codeine: Combaren.

Diclofenac is also used in many generic formulations.

Indomethacin [*53-86-1*], [1-(4-chlorobenzoyl)-5-methoxy-2-methyl-1*H*-indol-3-yl]-acetic acid, $C_{19}H_{16}ClNO_4$, M_r 357.79, *mp* 153–154 °C (crystals exhibiting polymorphism, *mp* for another form is 162 °C); sodium trihydrate [*74252-25-8*], $C_{19}H_{15}ClNNaO_4 \cdot 3H_2O$, M_r 433.82, pale yellow crystalline powder.

Synthesis [48, 110] (see next page).

Clinical use: Indomethacin is a nonsteroidal anti-inflammatory drug commonly used for the treatment of mild to moderate pain. Indomethacin is used in acute and chronic pain states like rheumatoid arthritis, osteoarthritis, joint and soft-tissue pain, dental pain, postoperative pain and dysmenorrhoea. Indomethacin is a COX-1 selective inhibitor with 10- to 60-fold selectivity compared to COX-2 [22, 23]. It is administered orally, rectally or topically (50–150 mg/d, maximal daily dose 200 mg) as well as ophthalmic solution.

The major side effects of indomethacin are gastrointestinal irritations and inflammation and central nervous system disturbances like depression, drowsiness, tinnitus, and convulsions. Indomethacin is absorbed after oral application reaching peak plasma concentrations after 2 h. It is bound to about 99 % to plasma proteins and shows a variable terminal half-life from 2.6 to 11.2 h in adults and up to 30 h in neonates.

Indomethacin is available as sodium, meglumine, or L-arginine salt or as prodrug (proglumetacin maleate).

Trade names: Elmetacin, Inflam, Wydora (Germany), Indocid (France, UK), Indocin (USA), Indolgina (Italy), Indocolir eye drops (Germany).

Prodrugs of indomethacin are acemetacin (see Section page 12) and proglumetacin maleate: Protaxon (Germany).

a) Merck & Co. process [111]:

b) Sumitomo process [112]:

Lonazolac [*53808-88-1*], [3-(4-chlorophenyl-1*H*-pyrazol-4-yl]acetic acid, $C_{17}H_{13}ClN_2O_2$, M_r 312.75, *mp* 150–151 °C; calcium salt (2 : 1) [*75821-71-5*], $C_{34}H_{24}CaCl_2N_4O_4$, M_r 663.57, *mp* 270–290 °C (decomp.).

Synthesis: The pyrazole-4-carbaldehyde synthesized according to the Vilsmeier synthesis is reduced to the alcohol, which is chlorinated. The chloro derivative is reacted with sodium cyanide to give the nitrile, which is hydrolyzed to lonazolac. The calcium salt, slightly soluble in water, is formed by adding calcium chloride to the free acid [48, 113–115].

Clinical use: Lonazolac [85] is a nonsteroidal anti-inflammatory drug used for the treatment of acute inflammatory pain conditions of joint and soft-tissue disorders as well as posttraumatic and postoperative pain. Lonazolac is used as calcium salt and is given orally (600 mg/d, initial dose up to 900 mg/d) or rectally (800 mg/d).

Trade names: Argun (Germany), Irritren (Austria, Belgium, Switzerland).

Lonazolac

Sulindac [*38194-50-2*], (*Z*)-5-fluoro-2-methyl-1-[4-(methylsulfinyl)phenyl]methylene-1*H*-indene-3-acetic acid, $C_{20}H_{17}FO_3S$, M_r 356.41, *mp* 182–185 °C (decomp.).

Synthesis [48, 116, 117] (see right column).

Clinical use: Sulindac [118] is a nonsteroidal anti-inflammatory drug used in the treatment of mild to moderate pain including musculoskeletal and joint disorders like rheumatoid arthritis, osteoarthritis, and gout. The main side effects are gastrointestinal disturbances and kidney stones [119]. Sulindac induces no relevant COX inhibition whereas the active metabolite sulindac sulfide inhibits both isoenzymes with some COX-1 preference [120], indicating that the pharmacological activity of sulindac probably results from its sulfide metabolite. Another metabolite, sulindac sulfone, induces apoptosis in tumor cells and sulindac is extensively studied for cancer treatment [121]. Sulindac is administered orally or rectally (200–400 mg/d).

Trade names: Arthrocine (France), Clinoril (Italy, UK, USA).

Sulindac

Tolmetin [*26171-23-3*], [1-methyl-5-(4-methylbenzoyl)-1*H*-pyrrol-2-yl]acetic acid, $C_{15}H_{15}NO_3$, M_r 257.28, *mp* 155–157 °C; sodium salt [*35711-34-3*], $C_{15}H_{14}NNaO_3$, M_r 279.27; sodium salt dihydrate [*64490-92-2*], $C_{15}H_{14}NNaO_3 \cdot 2\ H_2O$, M_r 315.30.

Synthesis [48, 122, 123] (see next page, left column).

Clinical use: Tolmetin [124] is a nonsteroidal anti-inflammatory drug used for the treatment of mild to moderate pain states in musculoskeletal, soft-tissue, and joint disorders like rheumatoid arthritis, osteoarthritis, and gout as well as juvenile rheumatoid arthritis. Tolmetin inhibits both isoforms of cyclooxygenase with some preference for COX-1 [125]. Tolmetin is administered orally, rectally, or topically (600–1800 mg/d). The peak plasma concentrations are reached within 30 to 60 min. Tolmetin shows a high plasma protein binding of 99 % and a biphasic plasma half-life of 1 to 2 and 5 h, respectively.

Trade name: Tolectin (Austria, Switzerland, UK, USA).

Tolmetin

Amtolmetin guacil (AMG, ester prodrug of tolmetin) [*87344-06-7*], 2-[2-[1-methyl-2-(4-methylbenzoyl)pyrrol-5-yl]acetamido]acetic acid 2-methoxyphenyl ester, 2-[2-[1-methyl-5-(4-methylbenzoyl)pyrrol-2-yl]-acetamido]acetic acid 2-methoxyphenyl ester, N-[(1-methyl-5-p-toluoylpyrrol-2-yl)acetyl]-glycine 2-methoxyphenyl ester, 1-methyl-5-p-toluoylpyrrole-2-acetamidoacetic acid guaicyl ester, $C_{24}H_{24}N_2O_5$, M_r 420.46, *mp* not reported.

Synthesis: The condensation of 1-methyl-5-(4-methylbenzoyl)pyrrole-2-acetic acid with glycine ethyl ester in the presence of carbonyldiimidazole and triethylamine in tetrahydrofuran gives the corresponding ethyl 2-[2-(1-methyl-5-(4-methylbenzoyl)-1*H*-pyrrol-2-yl)acetamido]acetate, which is hydrolyzed with NaOH in tetrahydrofuran – water yielding 2-[2-[1-methyl-5-(4-methylbenzoyl)pyrrol-2-yl]-acetamido]acetic acid. Finally, this compound is esterified with 2-methoxyphenol (guaiacol) in hot tetrahydrofuran with carbonyldiimidazole as catalyst [126].

Amtolmetin guacil

Clinical use: Amtolmetin guacil (AMG) is a non-steroidal anti-inflammatory drug developed by Sigma-Tau for the treatment of pain and inflammation. It acts similarly to tolmetin, and in preclinical trials displayed long-lasting anti-inflammatory and analgesic activity. Amtolmetin has a good gastrointestinal tolerability in humans [127] and does not induce gastric ulcers in the rat [128]. The good gastrointestinal tolerability and even a gastroprotective effect was related to an increase of endogenous NO via stimulation of inducible NO synthase in the gastric mucosa [129].

Trade name: Eufans (Italy).

Mofezolac [*78967-07-4*], 3,4-bis(4-methoxyphenyl)-5-isoxazoleacetic acid, 3,4-di-(*p*-methoxyphenyl)isoxazole-5-acetic acid, $C_{19}H_{17}NO_5$, M_r 339.35, *mp* 147.5 °C.

Synthesis:

a) The reaction of deoxyanisoin with hydroxylamine in methanol gives the corresponding 1,2-bis(4-methoxyphenyl)ethanone oxime, which is cyclized with ethyl acetate by means of *n*-butyllithium in tetrahydrofuran yielding 3,4-di(4-methoxyphenyl)-5-methylisoxazole. Finally, this compound is condensed with CO_2 with *n*-butyllithium as catalyst in tetrahydrofuran to yield mofezolac [130, 131]. The synthesis with $ClCO_2C_2H_5$ instead of CO_2 is described in [132, 133].

Mofezolac

b) Alternatively the corresponding 1,2-bis(4-methoxyphenyl)ethanone oxime can be condensed with (*E*)-methyl 3-methoxyacrylate with the aid of potassium *tert*-butyrate in *tert*-butanol to yield (*E*)-methyl 4,5-bis(4-methoxyphenyl)-5-oxopent-3-enoate, which is cyclized with hydroxyl amine. Subsequent treatment with oxygen in acetic acid yields mofezolac [132–135].

Clinical use: Yoshitomi (now Mitsubishi Pharma) has launched mofezolac, a COX-1 inhibitor [136] with preferential COX-1 inhibition [137] for the treatment of arthritis-related pain in Japan.

The compound is used in oral doses of 75 mg for the treatment of periarthritis, lumbago, neck-shoulder-arm syndrome and pain after surgery, trauma, or dental extraction.

Trade name: Disopain (Japan).

Bromfenac [*91714-94-2*], 2-amino-3-(4-bromobenzoyl)benzeneacetic acid, 2-[2-amino-3-(4-bromobenzoyl)phenyl]acetic acid, $C_{15}H_{12}BrNO_3$, M_r 334.17, monosodium salt [*91714-93-1*], $C_{15}H_{11}BrNNaO_3$, M_r 356.15, *mp* 284–286 °C (dec.), monosodium salt sesquihydrate [*120638-55-3*], $C_{15}H_{11}BrNNaO_3$ 3/2 H_2O, M_r 766.35.

Synthesis: The cyclization of 2-amino-4'-bromobenzophenone with ethyl 2-(methylthio)acetate with *tert*-butyl hypochlorite as catalyst in dichloromethane at 70 °C gives 7-(4-bromobenzoyl)-3-(methylthio)-2,3-dihydro-1*H*-indol-2-one, which is desulfurized by treatment with Raney nickel in THF yielding 7-(4-bromobenzoyl)-2,3-dihydro-1*H*-indol-2-one. Finally, this compound is hydrolyzed with refluxing 3 M aqueous NaOH and acidified with concentrated HCl [138–141].

Bromfenac

Clinical use: Bromfenac, used as the sodium salt, is a non-steroidal anti-inflammatory drug acting via inhibition of COX-1 and COX-2. It was launched in Japan in 2000 by Senju for topical treatment of ocular inflammation [142] and has been approved in the United States in 2006 for the treatment of pain following cataract surgery. It was used for the short-term treatment of acute pain, but it was withdrawn for this indication in June 1998 because of several post-marketing reports of severe hepatic failure [143–145].

The drug is rapidly absorbed and excreted. The drug's long duration of anti-inflammatory action despite its short half-life deserves further investigation.

Trade name: Xibrom (Japan, USA).

Nabumetone [*42924-53-8*], 4-(6-methoxy-naphthalen-2-yl)butan-2-one, $C_{15}H_{16}O_2$, M_r 228.29, *mp* 80 °C.

Synthesis: Condensation of 6-methoxy-2-naphthaldehyde with acetone in an aqueous solution of NaOH gives 4-(6-methoxy-2-naphthyl)-3-buten-2-one, which is reduced with H_2 over Pd-C in ethyl acetate [48, 146–149].

Nabumetone

Several additional ways for the synthesis of nabumetone are described. A short, simple, and economical process for large scale preparation avoiding hazardous chemicals or tedious work up procedures has been published [149].

Clinical use: Nabumetone [150] undergoes rapid first-pass metabolism to the active metabolite 6-methoxy-2-naphthylacetic acid (6-MNA). 6-MNA shows a balanced inhibition of both COX-1 and COX-2 [22]. Nabumetone is used for the treatment of pain and inflammation associated with osteoarthritis and rheumatoid arthritis. It shows a 99 % binding to plasma protein and an elimination half-life of up to 22 h with marked individual differences. Nabumetone is given orally (500–2000 mg/d).

Trade names: Listran (Spain), Nabuser (Italy), Relafen (USA), Relifex (UK).

2.5. Arylpropionic Acids

Flurbiprofen [*5104-49-4*], 2-(3′-fluorobiphenyl-4-yl)propionic acid, 2-fluoro-α-methyl[1,1′-biphenyl]-4-acetic acid, $C_{15}H_{13}FO_2$, M_r 244.26, *mp* 110–111 °C; sodium salt [*56767-76-1*], $C_{15}H_{12}FNaO_2$, M_r 266.25.

Synthesis [48, 151–154]:

a)

b)

Clinical use: Flurbiprofen is a nonsteroidal anti-inflammatory drug used for the treatment of pain and inflammation associated with musculoskeletal and joint disorders as well as neuralgia, dysmenorrhoea, and postoperative pain. Flurbiprofen is used as free acid or sodium salt and given orally or rectally (150–200 mg/d, max. 300 mg/d) and as ophthalmic solutions. Peak plasma concentration appears 1 to 2 h after oral application. The plasma protein binding is about 99.5 % and the elimination half-life is in the range of 3–5 h.

Use of flurbiprofen as antiplatelet agent after myocardial infarction is discussed [155].

In addition to COX inhibition, flurbiprofen induces weak inhibition of the transcription factors NFκ-B and AP-1 and inhibits cell proliferation, that is why its use in the treatment of cancer has been investigated [156].

Trade names: Ansaid (USA), Antadys, Cebutid (France), Dobedan (Germany), Froben (UK), Ocufen (UK, USA). Ocuflur eye drops (Germany)

Ibuprofen [*15687-27-1*], 2-(4-isobutylphenyl)propionic acid, $C_{18}H_{18}O_2$, M_r 206.28, *mp* 75–77 °C.

Synthesis [48, 157, 158] (see next page).

Several alternative processes are described in the literature.

Clinical use: Ibuprofen [159] is a nonsteroidal anti-inflammatory drug, commonly used for the treatment of mild to moderate pain. It is used in conditions like rheumatoid arthritis, osteoarthritis, joint and soft-tissue pain, dental pain, postoperative pain, dysmenorrhoea, and headache, including acute migraine attacks. Ibuprofen is given by oral, rectal, or topical administration (800–2400 mg/d) and with a lower dose (40 mg kg^{-1} d^{-1}) for the treatment of fever in children.

Ibuprofen shows the typical side effects of nonsteroidal anti-inflammatory drugs but seems to be better tolerated than other nonsteroidal anti-inflammatory drugs. This may be due to the balanced inhibition of COX-1 and COX-2 as seen in cultured human cells [23].

Ibuprofen is absorbed within 1 to 2 h after oral application, bound to plasma protein up to 99 % and shows a plasma half-life of about 2 h. Ibuprofen is a racemate, the active enantiomer, the S(+)-enantiomer, is available in some coun-

a) Boots process (industrial process):

b) Boots-Hoechst-Celanese process:

tries (dexibuprofen). Ibuprofen is given as free base or a variety of salts, esters, and other derivatives. Low-dose ibuprofen is available without prescription and has become one of the most popular OTC analgesics.

Trade names: Actren, Anco (Germany), Brufen (France, Italy, UK), Ibuprox (Spain), Imbun (Germany), Motrin (USA).

Combination with hydrocodone: Vicoprofen (USA).

Combination with oxycodone: Combunox (USA).

Ibuprofen is also marketed in many generic formulations.

Ketoprofen [*22071-15-4*], 2-(3-benzoylphenyl)propionic acid, 3-benzoyl-α-methylbenzeneacetic acid, $C_{16}H_{14}O_3$, M_r 254.28, *mp* 94 °C; lysine salt (1 : 1) [*57469-78-0*], $C_{16}H_{14}O_3 \cdot C_6H_{14}N_2O_2$, M_r 400.47; sodium salt [*57495-14-4*], $C_{16}H_{13}NaO_3$, M_r 276.27.

Synthesis [48, 160] (see next page).

Clinical use: Ketoprofen [161, 162] is a nonsteroidal anti-inflammatory drug used for the treatment of a variety of acute and chronic pain and inflammatory conditions including rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, postoperative pain, and dysmenorrhoea. It is administered orally, rectally, topically, or intramuscular (100–200 mg/d, maximal dose 300 mg/d) as sodium or lysine salt. Ketoprofen is given as racemate. The pharmacologically active isomer is mainly the S(+)-enantiomer, which is available in some countries as the trometamol (2-amino-2-(hydroxymethyl)-1,3-propanediol) salt. As compared to the racemate, absorption of the *S*(+)-isomer is said to be faster, leading to an earlier onset of action [163].

Ketoprofen

The peak plasma concentration after oral administration occurs within 2 h. Ketoprofen is bound to plasma protein up to 99 % and shows a plasma elimination half-life of 1.5 to 4 h.

Trade names: Ketocid (UK), Profénid (France), Orudis (Germany, Italy, USA).

S(+)-ketoprofen: Keral (UK).

Naproxen [*22204-53-1*], (+)-(*S*)-2-(6-methoxynaphthalen-2-yl)propionic acid, $C_{14}H_{14}O_3$, M_r 230.26, *mp* 155.3 °C (also reported as 152–154 °C), $[\alpha]_D$ + 66° (*c* = 1, $CHCl_3$); sodium salt [*26159-34-2*], $C_{14}H_{13}NaO_3$, M_r 252.25, *mp* 244–246 °C, $[\alpha]_D$ − 11° (*c* = 1, $CHCl_3$).

Synthesis [48, 164–166]:

For racemic resolution of naproxen the use of cinchonidine, *N*-alkyl-D-glucamine, dehydroabietylamine or (*S*)-α-phenylethylamine is described. For enzymatic cleavage of esters of racemic naproxen, cloned esterases, which are cheap and easy to produce, have been developed (production in a 100 t/a process is planned). Several other synthetic routes exist.

a) First large-scale manufacturing process of Syntex [167]:

Naproxen

b) Stereospecific Syntex process [168]:
The stereospecific Syntex process is an example using chiral technology to produce enantiomerically pure naproxen:

The asymmetric hydrogenation of 2-(6-methoxy-2-naphthyl)acrylic acid using ruthenium-2,2′-bis(diphenylphosphino)-1,1′-binaphthyl (BINAP) complexes yields also enantiomerically pure naproxen.

Clinical use: Naproxen [169] is a nonsteroidal anti-inflammatory drug used for the treatment of mild to moderate pain and inflammatory pain conditions like rheumatoid arthritis, osteoarthritis, soft-tissue disorders, postoperative pain, and dysmenorrhoea. In contrast to most other COX inhibitors, which are racemic mixtures, naproxen has been developed and is clinically used only as the (*S*)(+)-enantiomer. Naproxen is given orally or rectally (up to 1250 mg/d). The major side effects are gastrointestinal disturbances. To decrease gastrointestinal side effects, fixed combinations wih the proton pump inhibitor lansoprazole were developed.

Naproxen is available as free base, as sodium salt, and in combination with misoprostol for the reduction of the gastrointestinal side effects. For topical use, morpholinyl- and methylpiperazinylacyloxyalkyl prodrugs have been developed [170].

Trade names: Aleve (France, Germany), Anoprox (USA), Apranax (France, Germany), Naprosyn (UK, USA), Proxen (Germany), Synflex (UK).

Combination with lansoprazole: Prevacid, NapraPAC (USA).

Naproxen is also marketed in several generic formulations.

Tiaprofenic acid [*33005-95-7*], 2-(5-benzoylthiophen-2-yl)propionic acid, $C_{14}H_{12}O_3S$, M_r 260.31, *mp* 96 °C.

Synthesis [48, 171] (see right column, top).

Clinical use: Tiaprofenic acid [172] is a nonsteroidal anti-inflammatory drug used for the treatment of mild to moderate pain states in musculoskeletal, soft-tissue, and joint disorders as well as for postoperative pain treatment. Tiaprofenic acid is given as oral or rectal administration (600 mg/d) and as intramuscular injection of the trometamol (2-amino-2-(hydroxymethyl)-1,3-propanediol) salt. The main side effects are urinary tract symptoms like cystitis and bladder irritation [173].

Trade name: Surgam (France, Germany, UK).

Tiaprofenic acid

Zaltoprofen [*7411-43-6*], 2-(10-oxo-10,11-dihydrodibenzo[*b*,*f*]thiepin-2-yl)-propionic acid, α-methyl-10-oxo-10,11-dihydrodibenzo[*b*,*f*]thiepin-2-acetic acid, 10,11-dihydro-α-methyl-10-oxodibenzo[*bf*]thiepin-2-acetic acid, $C_{17}H_{14}O_3S$, M_r 298.36, *mp* 131-133 °C; (*S*)-enantiomer [*89482-01-9*], *mp* 129.5-131 °C), $[\alpha]_D^{25}$ +32.4° ($c = 1$, chloroform).

Synthesis: The cyclization of 5-(1-cyanoethyl)-2-(phenylthio)phenylacetic acid in presence of polyphosphoric acid at 120 °C gives 2-(10-oxo-10,11-dihydrodibenzo[*b*,*f*]thiepin-2-yl)propionitrile, which is then hydrolyzed with KOH in refluxing ethanol – water to zaltoprofen [174, 175].

Zaltoprofen

Clinical use: Zaltoprofen is a non-steroidal anti-inflammatory drug originated by Nippon Chemiphar and jointly developed with Zeria. It has been available on the market in Japan since 1993 for the relief of pain and inflammation resulting from arthritis deformations, periarthritis of the shoulder, neck-shoulder-arm syndrome, rheumatoid arthritis, lumbago, post-surgery pain, trauma, and tooth extraction and used in oral doses of 80 mg [176]. According to studies, the analgesic effects of zaltoprofen may involve the inhibition of bradykinin-2 receptor-mediated responses in primary afferent neurons [177, 178]. Although zaltoprofen is marketed as a racemate the anti-inflammatory activity resides in the (*S*)-enantiomer.

Trade name: Peon, Soleton (Japan).

Pirprofen [*31793-07-4*], *rac*-3-chloro-4-(2,5-dihydro-1*H*-pyrrol-1-yl)-α-methylbenzeneacetic acid, *rac*-3-chloro-4-(3-pyrrolin-1-yl)hydratropic acid, $C_{13}H_{14}ClNO_2$, M_r 251.71, *mp* 98-100 °C.

Synthesis:

a) Ethyl 4-nitrophenylacetate is methylated with NaH – CH_3I in dimethylformamide – toluene to form ethyl 2-(4-nitrophenyl)-propionate, which is reduced with H_2 over Pd/C in EtOH – H_2O to ethyl 2-(4-aminophenyl)propionate. This product is acetylated with acetic anhydride to yield ethyl 2-(acetylaminophenyl)propionate. Alternatively, ethyl 4-aminophenylacetate can be acetylated with acetic anhydride to ethyl 4-acetylaminophenylacetate followed by methylation with CH_3I and sodium in liquid NH_3 to give ethyl 2-(4-acetylaminophenyl)propionate [179, 180]. Ethyl 2-(4-acetylaminophenyl)propionate is chlorinated with Cl_2 in acetic acid to ethyl 2-(3-chloro-4-acetylaminophenyl)propionate. This intermediate is hydrolyzed with HCl in EtOH

to give ethyl 2-(3-chloro-4-aminophenyl)-propionate hydrochloride. The last step is the reaction of the preceding intermediate with *cis*-1,4-dichloro (or dibromo)-2-butene in dimethylformamide and Na_2CO_3 to ethyl 2-(3-chloro-4-(3-pyrrolinyl)phenyl)-propionate, followed by hydrolysis with KOH in EtOH – H_2O (see previous page).

b) 2,4-Dichloronitrobenzene is reacted with sodium diethyl methylmalonate in dimethylformamide to yield diethyl 2-(4-nitro-3-chlorophenyl)-2-methylmalonate, followed by hydrolysis, decarboxylation and esterification to form ethyl 2-(3-chloro-4-nitrophenyl)propionate. The latter is reduced as in route (a) to ethyl 2-(3-chloro-4-aminophenyl)propionate hydrochloride. Alternatively, diethyl 2-(4-nitro-3-chlorophenyl)-2-methylmalonate can be hydrogenated first to diethyl 2-(4-amino-3-chlorophenyl)-2-methylmalonate, and then hydrolyzed, decarboxylated and esterified again to form ethyl 2-(3-chloro-4-aminophenyl)propionate hydrochloride [179, 180] (see below).

Clinical use: Pirprofen is a nonsteroidal anti-inflammatory drug [181] and can be used for the treatment of post-operative pain, oncological pain, episodic headache attacks, and acute migraine [182]. There are reports on hepatic and renal intolerability [183–186] which precluded the further use.

Trade names: Rengasil (France, Belgium, Netherlands, Chile), Seflenyl.

Fenoprofen [*31879-05-7*], *rac*-α-methyl-3-phenoxybenzeneacetic acid, *rac-m*-phenoxyhydratropic acid, α-(d,l)-2-(3-phenoxyphenyl)propionic acid, $C_{15}H_{14}O_3$, M_r 242.27, viscous oil, $bp_{0.11}$ (0.147 hPa) 168-171 °C; calcium salt dihydrate, [*53746-45-5*], $C_{30}H_{26}CaO_6 \cdot 2H_2O$, M_r 558.64, *mp* 68-171 °C.

Synthesis: The condensation of 3-hydroxyacetophenone with bromobenzene yields 3-phenoxyacetophenone, which is reduced with sodium borohydride to 1-(3-phenoxyphenyl)ethanol. Bromination with phosphorus(III)bromide yields 1-(1-bromoethyl)-3-phenoxybenzene. After reaction with sodium cyanide the resulting 2-(3-phenoxyphenyl)propanenitrile is hydrolyzed to fenoprofen [187, 188]; for alternative syntheses see [189–191].

Fenoprofen

Clinical use: Fenoprofen [192–194] is a nonsteroidal anti-inflammatory drug used in oral doses of 300 mg as the calcium salt or in doses of 200–400 mg as free base for the treatment of moderate to severe pain and symptomatic treatment of acute and chronic rheumatoid arthritis and osteoarthritis. Enteric coated tablets of the Ca salt were developed to reduce gastrointestinal microbleeding [195]. The use of fenoprofen was associated with renal impairment [196] and allergic skin inflammation [197].

Trade names: Fepron (Italy), Nalfon (USA), Nalgesic (France).

Vedaprofen [*71109-09-6*], *rac*-4-cyclohexyl-α-methyl-1-naphthaleneacetic acid, *rac*-2-(4-cyclohexylnaphthalen-1-yl)propanoic acid, $C_{19}H_{22}O_2$, M_r 282.38, *mp* 150 °C.

Synthesis: The reaction of 1-cyclohexylnaphthalene and paraformaldehyde in the presence of concentrated hydrochloric acid and H_3PO_4 at 85 °C yields 1-chloromethyl-4-cyclohexylnaphthalene, which is transformed to (4-cyclohexylnaphthalen-1-yl)-acetonitrile by means of sodium cyanide in water acetone mixture as solvent. The hydrolysis of the nitrile with potassium hydroxide yields the sodium salt of (4-cyclohexylnaphthalen-1-yl)-acetic acid. After treatment with hydrochloric acid the free acid is converted to the corresponding (4-cyclohexyl-naphthalen-1-yl)-acetic acid methyl ester by means of acetyl chloride. Methylation with methyl iodide in the presence of *n*-butyllithium yields the desired vedaprofen after the standard work-up procedure [198].

Vedaprofen

Clinical use: Vedaprofen is a nonsteroidal anti-inflammatory drug with antipyretic and analgesic properties, based on inhibition of prostaglandin synthesis. Both enantiomers contribute to the biological and therapeutic actions of vedaprofen. Although vedaprofen was initially developed for human use, it is is now mainly used as a veterinary drug as oral gel [199] for the reduction of inflammation and pain associated with musculo-skeletal disorders in dogs [200] and horses and parenterally as the meglumine salt for the acute treatment of colic pain in horses [201]. In horses vedaprofen is administered orally at an initial dose of 2 mg/kg, followed by 1 mg/kg every 12 h for up to 14 days.

Trade name: Quadrisol.

Nepafenac [*78281-72-8*], 2-(2-amino-3-benzoylphenyl)acetamide, 2-amino-3-benzoylbenzeneacetamide, $C_{15}H_{14}N_2O_2$, M_r 254.29, *mp* 178.5-180 °C.

Synthesis: The reaction of (2-aminophenyl)-phenylmethanone and thiocarbamic acid *S*-methyl ester in the presence of 2,2-dimethylpropionyl chloride in methylene chloride at -65 °C and subsequent treatment with triethylamine at the same temperature yields the corresponding condensation product 2-(2-amino-3-benzoyl-phenyl)-2-methylsulfanylacetamide. Finally, nepafenac is obtained by reduction with Raney nickel in tetrahydrofuran [202, 203].

Clinical use: Nepafenac is a nonsteroidal antiinflammatory drug, that was launched by Alcon in 2005 for the treatment of pain and inflammation associated with cataract surgery, because it rapidly penetrates ocular tissues, and it is used locally as 1 % ophthalmic suspensions [204].

Nepafenac is an amide analog and a prodrug of amfenac (2-amino-3-benzoylbenzeneacetic acid), which is a COX-1 and COX-2 inhibitor [205]. Nepafenac is the first ophthalmic NSAID prodrug to receive FDA approval. It had originally been developed at Wyeth Consumer Healthcare [204, 206, 207].

Trade name: Nevanac.

Amfenac [*51579-82-9*], 2-amino-3-benzoylbenzeneacetic acid, 2-amino-3-benzoylphenylacetic acid, $C_{15}H_{13}NO_3$, M_r 255.28, *mp* 121-123 °C (dec.); sodium salt monohydrate [*61618-27-7*], $C_{15}H_{12}NNaO_3\ H_2O$, M_r 295.27, *mp* 254-255.5 °C.

Synthesis: The reaction of 1-aminoindolin-2-one with phenylacetone in presence of acetic acid in refluxing ethanol gives 1-(α-methylphenethylidieneimino)indolin-2-one, which by reaction with refluxing ethanolic hydrogen chloride affords ethyl α-(2-methyl-3-phenylindol-7-yl)acetate. The ozonolysis of this intermediate in acetic acid yields ethyl 2-acetamido-3-benzoylphenyl acetate, which is cyclized by refluxing with HCl in acetic acid to give 7-benzoylindolin-2-one. Alternatively, the hydrolysis of the ester ethyl α-(2-methyl-3-phenylindol-7-yl)acetate with KOH in refluxing water affords the corresponding acid, which can be ozonolyzed as before yielding 2-acetamido-3-benzoylphenylacetic acid. This acid can be cyclized to 7-benzoyl-1,3-dihydro-indol-2-one by refluxing with HCl in acetic acid as before [208–210].

2.6. Pyrazolinone Derivatives

Metamizol [*50567-35-6*], dipyrone[(1,5-dimethyl-3-oxo-2-phenyl-2,3-dihydro-1*H*-pyrazol-4-yl)methylamino]-methanesulfonic acid, $C_{13}H_{17}N_3O_4S$, M_r 311.36; sodium salt [*68-89-3*], $C_{13}H_{16}N_3NaO_4S$, M_r 333.34; sodium salt monohydrate [*50567-35-6*], $C_{13}H_{16}N_3NaO_4S \cdot H_2O$, M_r 351.36.

Synthesis [48, 211, 212] (see next page).

Clinical use: Metamizol [213, 214] is the water soluble sodium sulfonate of amidopyrine. After oral application it is rapidly hydrolyzed to 4-methylaminoantipyrine and metabolized to various active metabolites [215]. Metamizol has strong analgesic, spasmolytic, and antipyretic, but no anti-inflammatory properties. The exact mechanism of action is unknown but may include inhibition of prostaglandin synthesis. Inhibition of both COX isoenzymes by metamizol has been demonstrated only when very high concentrations of this drug were used, thus questioning the relevance of this activity.

COX inhibition may be induced by the metabolites, but this is not yet systematically investigated. Metamizol is used for the treatment of medium to severe pain, often in combination with opioids, for fever reduction and for the treatment of colic pain. It is given by mouth in doses of 500 mg up to 4 g daily, by intravenous or by rectal application. Metamizol is relatively free of acute side effects but in rare cases may cause severe and life-threatening allergic

reactions like agranulocytosis, allergic skin reactions, and allergic shock. The compound is not used in the UK, USA, and in Scandinavian countries.

Metamizol sodium

Trade names: Analgin, Novalgin (Germany, Austria, Switzerland).

Metamizol is also marketed in several generic formulations.

Propyphenazone [*479-92-5*], 1,2-dihydro-1,5-dimethyl-4-(1-methylethyl)-2-phenyl-3*H*-pyrazol-3-one, $C_{14}H_{18}N_2O_3$, M_r 230.31, *mp* 103 °C.

Synthesis [48, 216, 217]:

Propyphenazone

Clinical use: Propyphenazone [218, 219] is a derivative of phenazone and has a similar analgesic and antipyretic action. It is used as a monocompound as well as in multi-ingredient preparations.

Trade name: Demex (Germany).

Multi-ingredient preparation: Saridon (Germany).

2.7. Acidic Enolic Compounds

2.7.1. Pyrazolidine-3,5-diones

Kebuzone [*853-34-9*], 4-(3-oxobutyl)-1,2-diphenyl-pyrazolidine-3,5-dione, $C_{19}H_{18}N_2O_3$, M_r 322.36, *mp* 115.5–116.5 °C or 127.5–128.5 °C, depending on crystal form.

Synthesis [158, 220, 221]:

Kebuzone

Clinical use: Kebuzone [222] is a non-steroidal anti-inflammatory drug used for the treatment of acute and chronic pain and inflammation states like musculoskeletal, joint, and soft-tissue disorders. Kebuzone is administered orally, rectally, or intramuscular (up to 1500 mg/d initial dose, 250–500 mg/d maintenance dose).

Trade names: Ketazon (Austria), Chetopir (Italy).

Mofebutazone [*2210-63-1*], 4-butyl-1-phenylpyrazolidine-3,5-dione, $C_{13}H_{16}N_2O_2$, M_r 232.28, *mp* 102–103 °C; sodium salt [*41468-34-2*], $C_{13}H_{15}N_2NaO_2$, M_r 254.27.

Synthesis [48, 223, 224]:

Mofebutazone

Clinical use: Mofebutazone [225] is a non-steroidal anti-inflammatory drug used as sodium salt for the treatment of mild to moderate pain including inflammatory and degenerative rheumatic disorders and musculoskeletal pain. Mofebutazone can be given by oral, rectal (900–1200 mg/d), or intramuscular administration (650 mg/d).

Trade name: Mofesal (Germany).

Oxyphenbutazone [*129-20-4*], oxyphenylbutazone, 4-butyl-1-(4-hydroxyphenyl)-2-phenylpyrazolidine-3,5-dione, $C_{19}H_2ON_2O_3$, M_r 324.37, *mp* 124–125 °C; monohydrate [*7081-38-1*], $C_{19}H_{20}N_2O_3 \cdot H_2O$, M_r 342.40, *mp* 96 °C.

Synthesis [48, 226]:

Oxyphenbutazone

Clinical use: Oxyphenbutazone is a non-steroidal anti-inflammatory drug, which was used by oral, rectal, or topical administration (400 - 600 mg/d) for the acute treatment of ankylosing spondylitis, chronic polyarthritis, and gout. Because of a high incidence of severe side effects including disturbances of the hematopoietic system like agranulocytosis and aplastic anemia [233] the compound is no longer used. Oxyphenbutazone is a metabolite of phenylbutazone.

Phenylbutazone [*50-33-9*], 4-butyl-1,2-diphenylpyrazolidine-3,5-dione, $C_{19}H_{20}N_2O_2$,

M_r 308.37, *mp* 105 °C; sodium salt [*129-18-0*], $C_{19}H_{19}N_2NaO_2$, M_r 331.36; calcium salt (2 : 1) [*36298-23-4*], $C_{38}H_{36}CaN_4O_4$, M_r 656.83; piperazine salt (1 : 1) [*4985-25-5*], $C_{19}H_{20}N_2O_2 \cdot C_4H_{10}N_2$, M_r 395.51, *mp* 140–141 °C.

Synthesis [48, 228]:

Phenylbutazone

Clinical use: Phenylbutazone [229] is a nonsteroidal anti-inflammatory drug used for the acute treatment of ankylosing spondylitis, chronic polyarthritis, and gout. Because of severe side effects including disturbances of the hematopoietic system like agranulocytosis and aplastic anemia [230] the use is limited to conditions in which other nonsteroidal anti-inflammatory drugs do not show sufficient efficacy. Phenylbutazone is given as oral, rectal, intramuscular or topical formulation (up to 600 mg/d initial dose, up to 400 mg/d maintenance dose). The peak plasma concentration is reached 2 h after oral application. Phenylbutazone is bound to 98 % to plasma protein. Oxyphenbutazone is formed as an active metabolite of phenylbutazone.

Trade names: Butazolidin (France, Germany, UK, USA), Ambene (Germany).

2.7.2. Arylsulfonamides (Oxicames)

The oxicams are a group of nonsteroidal anti-inflammatory agents containing a 2*H*-1,2-benzothiazine-3-carboxamide 1,1-dioxide moiety as common structural entity (for Meloxicam see Section 2.9.1).

Isoxicam [*34552-84-6*], 4-hydroxy-2-methyl-1,1-dioxo-1,2-dihydro-1λ^6-benzo[*e*][1,2]thiazine-3-carboxylic acid isoxazo-3-ylamide, 4-hydroxy-2-methyl-*N*-(5-methyl-3-isoxazolyl)-2*H*-1,2-benzothiazine-3-carboxamide 1,1-dioxide, $C_{14}H_{13}N_3O_5S$, M_r 335.34, *mp* 265–271 °C (decomp.); sodium salt, $C_{14}H_{12}N_3NaO_5S$, M_r 343.29, *mp* 270–272 °C.

Synthesis [48, 231–233]:

Isoxicam

Clinical use: Isoxicam [234] is a nonsteroidal anti-inflammatory drug withdrawn from the market as a consequence of reports of fatal skin reaction.

Lornoxicam [*70374-39-9*], 6-chloro-4-hydroxy-2-methyl-1,1-dioxo-1,2-dihydro-1λ^6-thieno[2,3-*e*][1,2]thiazine-3-carboxylic acid pyridin-2-ylamide, 6-chloro-4-hydroxy-2-methyl-*N*-(2-pyridyl)-2*H*-thieno[2,3-*e*]-1,2-thiazine-3-carboxamide 1,1-dioxide, $C_{13}H_{10}ClN_3O_4S_2$, M_r 371.81, *mp* 225–230 °C (decomp.).

Synthesis: Sulfonation of 2,5-dichlorothiophene with $ClSO_3H/SOCl_2$ gives 2,5-dichlorothiophene-3-sulfonyl chloride, which by reaction with methylamine in $CHCl_3$ yields the corresponding methylamide. The carboxylation with butyl lithium and CO_2 in ether affords 5-chloro-3-(*N*-methylsulfamoyl)thiophene-2-carboxylic acid,

which is esterified with PCl_5 and methanol to the methyl ester. Condensation with methyl iodoacetate by means of NaH in DMF gives methyl 5-chloro-3-[*N*-(methoxycarbonylmethyl)-*N*-methylsulfamoyl]thiophene-2-carboxylate, which is cyclized with sodium methoxide in methanol yielding methyl 6-chloro-4-hydroxy-2-methyl-2*H*-thieno[2,3-*e*]-1,2-thiazine-3-carboxylate-1,1-dioxide. Finally this compound is treated with 2-aminopyridine in refluxing xylene [235].

Lornoxicam

Clinical use: Lornoxicam [236] is a non-steroidal anti-inflammatory drug with a strong and balanced inhibition of COX-1 and COX-2 in cultured human cells [23]. In addition, lornoxicam inhibits inducible nitric oxide synthase and interleukin-6, both of which could contribute to its potent anti-inflammatory and analgesic action [237]. It is used orally (8–24 mg/d) for the treatment of mild to moderate pain including postoperative pain, rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis [238]. Lornoxicam shows a high binding to plasma protein and in contrast to other oxicams a short plasma half-life of 3 to 5 h [236].

Trade names: Telos (Germany), Taigalor (Italy), Xefo (Austria, Denmark, Italy, Switzerland, UK).

Piroxicam [*36322-90-4*], 4-hydroxy-2-methyl-1,1-dioxo-1,2-dihydro-1λ^6-benzo-[*e*][1,2]thiazine-3-carboxylic acid pyridin-2-ylamide, 4-hydroxy-2-methyl-*N*-2-pyridinyl-2*H*-1,2-benzothiazine-3-carboxamide 1,1-dioxide, $C_{15}H_{13}N_3O_4S$, M_r 331.35, *mp* 198–200 °C.

Synthesis [239–243, 251]:

Piroxicam

Clinical use: Piroxicam [244] is a non-steroidal anti-inflammatory drug used for the treatment of mild to moderate acute and chronic pain and inflammation including musculoskeletal, soft-tissue, and joint disorders like ankylosing spondylitis, chronic polyarthritis, and gout [245]. Piroxicam shows a 600-fold selectivity for COX-1 compared to COX-2 in cultured animal cells [246]. Piroxicam is administered orally, rectally, intramuscular, or topically (10–30 mg/d, maximal initial dose 40 mg/d) as the free base, as complex with beta-cyclodextrine, and as cinnamate or pivalate. After oral administration, piroxicam reaches peak plasma concentration after 3 to 5 h, shows a 99 % binding to plasma protein and a long half-life of about 50 h.

Trade names: Brexidol (EU, USA), Brexin (Franc, Italy), Feldéne (France), Felden (Germany), Feldene (UK, USA).

Piroxicam is also marketed in several generic formulations.

Tenoxicam [*59804-37-4*], 4-hydroxy-2-methyl-1,1-dioxo-1,2-dihydro-1λ^6-thieno[2,3-*e*][1,2]thiazine-3-carboxylic acid pyridin-2-ylamide, 4-hydroxy-2-methyl-*N*-2-pyridinyl-2*H*-thieno[2,3-*e*]-thiazine-3-carboxamide 1,1-dioxide, $C_{13}H_{11}N_3O_4S_2$, M_r 337.38, *mp* 209–213 °C (decomp.).

Tenoxicam

Synthesis: The reaction of methyl 3-hydroxythiophene-2-carboxylate with PCl_5 in refluxing CCl_4 gives 3-chlorothiophene-2-carboxylic acid, which by treatment with $NaHSO_3$ and Cu in aqueous alkaline solution at 143 °C in a pressure vessel is converted into 3-sulfothiophene-2-carboxylic acid. Its esterification with refluxing methanol affords methyl-3-sulfothiophene-2-carboxylate, which by reaction with refluxing $SOCl_2$ yields methyl-3-chlorosulfonylthiophene-2-carboxylate. The following condensation with sarcosine ethyl ester in hot $CHCl_3$ gives 3-(*N*-ethoxycarbonylmethyl-*N*-methylsulfamoyl)thiophene-2-carboxylate, which is cyclized by treatment with sodium methoxide in refluxing methanol affording 3-ethoxycarbonyl-4-hydroxy-2-methyl-2*H*-thieno-[2,3-*e*]-1,2-thiazine 1,1-dioxide. Finally this compound is condensed with 2-aminopyridine in refluxing toluene [48, 243, 247].

Clinical use: Tenoxicam [248] is a nonsteroidal anti-inflammatory drug used for the treatment of mild to moderate pain states in musculoskeletal, soft-tissue, and joint disorders like rheumatoid arthritis, osteoarthritis and gout. Tenoxicam shows a balanced inhibition of both COX-1 and COX-2 in cultured human cells [23]. Tenoxicam is administered orally, rectally, or intramuscular (20 mg/d, maximal dose 40 mg/d). Peak plasma concentration appears within 1 to 6 h after administration depending on food intake. Tenoxicam is bound to plasma protein to 98.5 % and shows a long plasma elimination half-life of 70 to 90 h.

Trade names: Mobiflex (UK), Tilcotil (France, Italy, Switzerland).

2.8. Other Structures

Ketorolac [*74103-06-3*], 5-benzoyl-2,3-dihydro-1*H*-pyrrolizine-1-carboxylic acid, $C_{15}H_{13}NO_3$, M_r 255.27, *mp* 160–161 °C; tromethamine salt (1 : 1) [*74103-07-4*], $C_{15}H_{13}NO_3 \cdot C_4H_{11}NO_3$, M_r 376.41, (+)-form *mp* 174 °C, $[\alpha]_D$ + 173° (*c* = 1, CH_3OH), (−)-form *mp* 169–170 °C, $[\alpha]_D$ − 176° (*c* = 1, CH_3OH); monosodium salt [*110618-38-7*], $C_{15}H_{12}NNaO_3$, M_r 277.26.

Synthesis: Benzoylation of 2-methylthiopyrrole with *N*,*N*-dimethylbenzamide in the presence of $POCl_3$ in refluxing CH_2Cl_2 gives 5-benzoyl-2-methylthiopyrrole, which is condensed with spiro[2,5]-5,7-dioxa-6,6-dimethyloctane-4,8-dione by means of NaH in DMF. Oxidation of this product with *m*-chloroperbenzoic acid in CH_2Cl_2 affords the sulfone, which is submitted to methanolysis with methanol and HCl giving 1-(3,3-dimethoxycarbonylpropyl)-2-methanesulfonyl-5-benzoylpyrrole. Cycliza-

tion with NaH in DMF yields dimethyl-5-benzoyl-1,2-dihydro-3*H*-pyrrolo[1,2-α]pyrrole-1,1-dicarboxylate, which is finally hydrolyzed and decarboxylated with KOH in refluxing methanol [48, 249–253].

Clinical use: Ketorolac [254] is a nonsteroidal anti-inflammatory drug mainly used for the treatment of moderate to severe postoperative pain. Ketorolac shows a balanced inhibition of COX-1 and COX-2 in cultured human cells [23]. Ketorolac is mostly used as the tromethamine salt. Due to a number of severe side effects including gastrointestinal disturbances, impairment of liver functions, renal failures, skin irritations, and other hypersensitivity reaction it has been withdrawn in many countries.

Trade names: Acular (UK, USA), Droal (Spain), Tora-Dol (France, Italy), Toradol (UK, USA).

Oxaprozine [*21256-18-8*], 3-(4,5-diphenyl-oxazol-2-yl)propionic acid, $C_{18}H_{15}NO_3$, M_r 293.32, *mp* 160.5–161.5 °C.

Synthesis [255–257]:

Clinical use: Oxaprozine [257] is a nonsteroidal anti-inflammatory drug used for the treatment of mild to moderate pain including rheumatoid arthritis and osteoarthritis. Oxaprozine shows slow elimination kinetics with an elimination half-life of about 24 h. It is given orally (600–1200 mg/d, maximum dose 1800 mg/d).

Trade names: Deflam (South Africa), Daypro (USA).

2.9. COX-2 Inhibitors

2.9.1. Nonselective COX-2 Inhibitors

Etodolac [*41340-25-4*], (1,8-diethyl-1,3,4,9-tetrahydropyrano[3,4-*b*]indol-1-yl)-acetic acid, $C_{17}H_{21}NO_3$, M_r 287.35, *mp* 145–148 °C.

Synthesis [258–261]:

Clinical use: Etodolac [262] shows a ten-fold selectivity for COX-2 compared to COX-1 in human whole blood and belongs to the first generation of COX-2 inhibitors [22]. Etodolac is a racemate with an active (*S*)-enantiomer and an inactive (*R*)-enantiomer. It is used for the treatment of mild to moderate acute and chronic pain including rheumatoid arthritis and osteoarthritis. Clinical data indicate fewer gastrointestinal side-effects in comparison to naproxen [51, 264]. Etodolac is used in oral slow and immediate release preparations and applied in doses of 600–1200 mg/d. Peak plasma concentrations are reached within 2 h. Etodolac shows a 99 % binding to plasma protein and an elimination half-life of about 7 h.

Trade name: Lodine (USA, UK, France).

Meloxicam [*71125-38-7*], 4-hydroxy-2-methyl-1,1-dioxo-1,2-dihydro-1λ^6-benzo[*e*][1,2]thiazine-3-carboxylic acid (5-methyl thiazol-2-yl)amide, 4-hydroxy-2-methyl-*N*-(5-methyl-2-thiazoyl)-2*H*-1,2-benzothiazine-3-carboxamide 1,1-dioxide, $C_{14}H_{13}N_3O_4S_2$, M_r 351.40, *mp* 264 °C (decomp.).

Synthesis: Reaction of benzothiazolo-3(2*H*)-one-1,1-dioxide with methyl chloroacetate gives the methyl 2(3*H*)-acetate derivative, which is isomerized with sodium methoxide in toluene-*tert*-butanol yielding methyl 4-hydroxy-2*H*-1,2-benzothiazine-3-carboxylate-1,1-dioxide. Subsequent methylation with methyl iodide in methanol yields the 2-methyl compound. Finally this compound is treated with 2-amino-5-methylthiazole in xylene [48, 265, 266].

Meloxicam

Clinical use: Meloxicam [267] shows a ten-fold selectivity for COX-2 compared to COX-1 in human whole blood and belongs to the first generation of COX-2 selective drugs [22]. Meloxicam is used for the acute and chronic treatment of mild to moderate pain including arthritis and ankylosing spondylitis. Meloxicam shows central antinociceptive effects in rats which seems to be independent from the COX inhibiting properties [268].

Meloxicam is given by oral administration (7.5–15 mg/d). It shows an elimination half-life of 20 h.

Trade names: Mobec (Germany), Mobic (Italy, UK, USA), Movalis (Spain).

Nimesulide [*51803-78-2*], *N*-(4-nitro-2-phenoxyphenyl)methanesulfonamide, $C_{13}H_{12}N_2O_5S$, M_r 308.05, *mp* 143–144.5 °C.

Synthesis [48, 269]:

Nimesulide

Clinical use: Nimesulide [270] is a first-generation COX-2 inhibitor with a 5- to 100-fold selectivity for COX-2 compared to COX-1, depending on the assay system [22, 23]. It is used for the short-term treatment of inflammatory conditions, fever, and pain, including musculoskeletal and joint disorders. In addition to COX inhibition nimesulide reduces the production of the pro-inflammatory cytokine TNF-α under inflammatory conditions [271].

Nimesulide is available in oral or rectal formulations (up to 400 mg/d).

The use of nimesulide has been reported to be associated in some cases with hepatic failure [272, 273] and the compound was withdrawn from the market in several countries.

Trade names: Aulin (Italy, Switzerland), Nexen (France), Guaxan (Spain, withdrawn).

2.9.2. Selective COX-2 Inhibitors (Coxibs)

Celecoxib [*169590-42-5*], 4-(5-*p*-tolyl-3-trifluoromethylpyrazol-1-yl)-benzenesulfonamide, $C_{17}H_{14}F_3N_3O_2S$, M_r 381.37, *mp* 157–159 °C (pale yellow solid).

Synthesis: Condensation of 4-methylacetophenone with ethyl trifluoroacetate in refluxing methanol using sodium methoxide as catalyst gives 4,4,4-trifluoro-1-(4-methylphenyl)butane-1,3-dione, which is cyclized with 4-hydrazinophenylsulfonamide in refluxing ethanol [488, 493].

Celecoxib

Clinical use: Celecoxib [166] is a second-generation selective COX-2 inhibitor and was the first drug of this group to reach the market. The selectivity for COX-2 compared to COX-1 is about 375-fold in human recombinant enzyme preparations and about eight-fold in a whole blood assay. Celecoxib has been approved in 1999 in the USA and is now used for the treatment of rheumatoid arthritis and osteoarthritis, ankylosing spondylitis, acute pain and primary dysmenorrhoea all over the world.

Celecoxib is further approved for the use in familial adenomatous polyposis in the US and leads to a reduction in the number of colorectal polyps in these patients [276].

The use of celecoxib is associated with a reduced incidence of gastroduodenal ulcers in comparison to naproxen [277], ibuprofen, and diclofenac [278] in arthritic patients. Because of a greater COX-1 inhibiting component as compared to the newer highly COX-2 selective compounds such as valdecoxib, rofecoxib, and paricoxib, cardiovascular side effects of celecoxib are less prominent and the compound avoided withdrawal from the market [279]. Nevertheless

celecoxib should be used with appropriate precaution.

Plasma peak concentrations are achieved within 2 h and the elimination half-life is about 12 h. Celecoxib is given orally (200–400 mg/d).

Trade names: Celebrex (EU, USA), Onsenal (EU).

Etoricoxib [*202409-33-4*], [*202409-40-3*] (mono HCl), 5-chloro-3-[4-(methyl-sulfonyl)phenyl]-2-(6-methylpyridin-3-yl)pyridine, 5-chloro-6′-methyl-3-(4-[methylsulfonyl)phenyl]-2,3′-bipyridine, $C_{18}H_{15}ClN_2O_2S$, M_r 358.848, crystals, *mp* 271.5-138.1 °C (136.7 °C DSC onset).

Synthesis [280–284]:

a) Synthesis via dichloropyridine:
   i) The bromination of 5-chloro-2-hydroxypyridine with Br_2 in acetic acid gives 3-bromo-5-chloro-2-hydroxypyridine, which is treated with benzyl bromide and Ag_2CO_3 in hot benzene to yield the benzyl ether 2-(benzyloxy)-3-bromo-5-chloropyridine. Condensation of 2-(benzyloxy)-3-bromo-5-chloropyridine with 4-(methylsulfanyl)phenylboronic acid with the aid of $Pd(PPh_3)_4$ and Na_2CO_3 in refluxing ethanol/benzene affords 2-(benzyloxy)-5-chloro-3-[4-(methylsulfanyl)phenyl]pyridine, which is oxidized with OsO_4 and sodium sulfite to furnish sulfone 2-(benzyloxy)-5-chloro-3-[4-(methylsulfonyl)phenyl]-pyridine. Treatment of 2-(benzyloxy)-5-chloro-3-[4-(methylsulfonyl)phenyl]pyridine with trifluoroacetic acid (TFA) provides the 2-hydroxypyridine derivative, which is reacted with $POCl_3$ to yield 2,5-dichloro-3-[4-(methylsulfonyl)phenyl]-pyridine.
   ii) Bromination of 2-amino-5-chloropyridine with Br_2 in acetic acid provides 2-amino-3-bromo-5-chloropyridine, which is condensed with 4-(methylsulfanyl)phenylboronic acid in the presence of $Pd(PPh_3)_4$ and Na_2CO_3 in refluxing ethanol/benzene to give 5-chloro-3-[4-(methylthio)phenyl]pyridin-2-amine. Oxidation of 5-chloro-3-[4-(methylthio)phenyl]pyridin-2-amine with OsO_4 as before yields the sulfone 5-chloro-3-[4-(methylsulfonyl)phenyl]-pyridin-2-amine, which is converted into 2,5-dichloro-3-[4-(methylsulfonyl)phenyl]pyridine by treatment first with $NaNO_2$ and HCl and then chlorination with $POCl_3$ [280, 281].
   iii) 2,5-dichloro-3-[4-(methylsulfonyl)phenyl]-pyridine is condensed with either trimethyl(6-methyl-3-pyridyl)tin or the boronate ester lithium salt by means of $Pd(PPh_3)_4$ to afford etoricoxib .The metalated pyridine 2-methyl-5-(trimethylstannyl)pyridine is obtained by esterification of 3-hydroxy-6-methylpyridine with trifluoromethanesulfonic (triflic) anhydride to give the corresponding triflate 6-methylpyridin-3-yl trifluoromethanesulfonate, which is treated with hexamethylditin to afford the target tin intermediate 2-methyl-5-(trimethylstannyl)pyridine. The boronate lithium salt is prepared by treatment of 5-bromo-2-methylpyridine with *n*-butyl lithium followed by addition of triisopropyl borate [281] (see next page).

b) In addition, etoricoxib is obtained by several related ways via the ketosulfone key intermediate 1-(6-methylpyridin-3-yl)-2-[4-(methylsulfonyl)phenyl]ethanone, which can also be synthesized by several different routes:
   i) Reaction of ketosulfone 1-(6-methylpyridin-3-yl)-2-(4-[methylsulfonyl)phenyl]ethanone with 2-chloro-1,3-bis(dimethylamino)trimethinium hexafluorophosphate salt in the presence of an equimolar amount of potassium *tert*-butoxide, followed by treatment with acetic/trifluoroacetic acid and then heating at reflux with an excess of ammonium hydroxide. The 2-chloro-1,3-bis(dimethylamino)trimethinium hexafluorophosphate salt is obtained by reaction of chloroacetic acid with hot dimethylformamide and $POCl_3$, and then the reaction mixture is treated with 5 N NaOH and hexafluorophosphoric acid in water.
   ii) Cyclization of ketosulfone 1-(6-methylpyridin-3-yl)-2-(4-[methylsulfonyl)phenyl]ethanone with 2-chloromalondialdehyde (A: X=OH), or by cyclization of ketosulfone 1-(6-methylpyridin-3-yl)-2-[4-(methylsulfo-

nyl)phenyl]ethanone with aminoacrolein (B: X=NH_2) in the absence of ammonium acetate. The cyclization of the lithium enolate of ketosulfone 1-(6-methylpyridin-3-yl)-2-(4-(methylsulfonyl)phenyl)ethanone with 2,3-dichloroacrolein (C: X=Cl) – obtained by treatment of chloromalondialdehyde with oxalyl chloride and dimethyl formamide in toluene – followed by reaction with ammonium acetate or anhydrous ammonia yield also the desired etoricoxib.

iii) Etoricoxib can also be obtained by cyclization of the aniline derivative 2-chloro-3-

phenylaminopropenal and ammonium acetate in hot propionic acid [280–284].

Clinical use: Etoricoxib [280, 285] is a third-generation COX-2 inhibitor with a 100-fold selectivity for COX-2 in a whole blood assay. The selectivity ratio is higher than with other coxibs such as rofecoxib, valdecoxib, or celecoxib.

The compound was shown to be active in rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, postoperative pain, and in chronic low back pain. Further positive results were seen in patients with acute gout and against primary dysmenorrhoea [286].

Etoricoxib is used in oral doses of 60–120 mg/d. The compound is rapidly absorbed and peak plasma concentrations are achieved within 1.0 to 1.5 h after administration in healthy volunteers [287]. The elimination half-life is about 15 h. Etoricoxib is metabolized to about 60 % by members of the cytochrome P450 3A family [288]. In vitro studies give no evidence for active metabolites with respect to COX-1 and COX-2 inhibition [289].

Etoricoxib is generally well tolerated and induces less gastrointestinal side effects than conventional COX-1 inhibitors or non-COX selective NSAIDs [290]. Renal tolerability is similar to conventional COX-1 inhibitors [291]. According to its COX-2 selectivity, etoricoxib has an increased risk of cardiovascular side effects [292] and should only be used with appropriate precautions.

Trade name: Arcoxia (EU, USA).

Lumiracoxib [*220991-20-8*], 2-[2-(2-chloro-6-fluorophenylamino)-5-methylphenyl]acetic acid, $C_{15}H_{13}ClFNO_2$, M_r 293.72, *mp* 158-159 °C.

Synthesis [61, 294, 295]: The partial reduction of 4-methylanisole with sodium in liquid ammonia/THF/ethanol gives the enol ether 3-methoxy-6-methylcyclohexa-1,4-diene, which is condensed with 2-chloro-6-fluoroaniline in presence of $TiCl_4$ in chlorobenzene/THF to yield (*E*)-2-chloro-6-fluoro-*N*-(4-methylcyclohex-2-enylidene)benzenamine, which, without isolation, is aromatized with I_2 in AcOH/THF to provide *N*-(2-chloro-6-fluorophenyl)-*N*-(4-methylphenyl)amine. The acylation of this intermediate with 2-chloroacetyl chloride at 90 °C affords the 2-chloro-*N*-(2-chloro-6-fluorophenyl)-*N*-*p*-tolylacetamide, which is cyclized by means of $AlCl_3$ by heating at 160 °C to afford 1-(2-chloro-6-fluorophenyl)-5-methylindolin-2-one. Finally, this compound is hydrolyzed with NaOH in refluxing ethanol/water and acidified with 1 *N* HCl to give lumiracoxib. Alternatively, the intermediate *N*-(2-chloro-6-fluorophenyl)-*N*-(4-methylphenyl)amine can also be obtained by condensation of 2-chloro-*N*-(4-methylphenyl)acetamide with 2-chloro-6-fluorophenol using K_2CO_3 in isopropanol to yield 2-(2-chloro-6-fluorophenoxy)-*N*-(4-methylphenyl)acetamide, which is treated with MeONa in methanol to obtain the target secondary amine Lumiracoxib [61, 294].

An alternative synthesis of lumiracoxib involves the coupling of *N*,*N*-dimethyl-5-methyl-2-iodophenylacetamide with 2-chloro-6-fluoroaniline in the presence of copper powder, copper(I) iodide and anhydrous potassium carbonate, and refluxing in xylene for 48 h. This synthetic route includes the following steps: The reduction of 2-iodo-5-methylbenzoic acid with BH_3/THF in THF gives 2-iodo-5-methylbenzyl alcohol, which is treated with refluxing 48 % HBr to yield the benzyl bromide. Reaction of the benzyl bromide with NaCN in ethanol/water affords the phenylacetonitrile, which is hydrolyzed with NaOH in refluxing EtOH/water to provide the phenylacetic acid. Reaction of 2-(2-iodo-5-methylphenyl)acetic acid with $SOCl_2$ in refluxing dichloromethane gives the corresponding acyl chloride, which is treated with dimethylamine in diethyl ether/THF to yield 2-(2-iodo-5-methylphenyl)-*N*,*N*-dimethylacetamide. Condensation of this intermediate with 2-chloro-6-fluoroaniline by means of Cu powder, Cu_2I_2 and K_2CO_3 in refluxing xylene affords 2-[2-(2-chloro-6-fluorophenylamino)-5-methylphenyl]-*N*,*N*-dimethylacetamide, which is finally hydrolyzed with NaOH in refluxing butanol/water to give lumiracoxib [61, 294, 295].

Clinical use: Lumiracoxib [296] is a novel COX inhibitor with the highest COX-2 selectivity of all coxibs. The compound is structurally related to the phenylacetic acid COX inhibitors, has weakly acidic properties and is devoid of the sulfonamide or methylsulfone group of the other coxibs. The compound showed clinical efficacy against osteoarthritis [297] and rheumatoid arthritis [298] and inhibited acute pain related to primary dysmenorrhoea, dental or orthopedic surgery, or tension-type headache [299].

The compound is well tolerated and gastrointestinal side effects were significantly lower than after treatment with COX-1 inhibitors like ibuprofen or naproxen [300, 301] The meta-analysis of all clinical trials in osteoarthritis and rheumatoid arthritis gave no indication of an increased risk of cardiovascular side effects [302]. Liver function tests showed a moderate and reversible increase in liver enzymes [303].

Lumiracoxib has a high oral bioavailability of about 74 %, is rapidly absorbed, reaches its peak plasma concentrations within 2 h and is strongly bound to plasma protein. The compound is strongly metabolized, is devoid of active metabolites and has a plasma elimination half-life of about 4 h [304]. Despite the short half-life, a once-daily administration in doses of 100–400 mg is recommended. A dose of 100 mg is used for the symptomatic relief of osteoarthritis and 400 mg for short-term relief of moderate to severe pain, associated with dental or orthopedic surgery. As with other COX-2 inhibitors, the compound should be used with appropriate precaution.

Trade name: Prexige (EU, USA).

Parecoxib [*198470-84-7*], (free acid) [*198470-85-8*], *N*-(4-(5-methyl-3-phenyl-isoxazol-4-yl)phen-ylsulfonyl)propionamide sodium salt $C_{19}H_{17}N_2O_4SNa$, M_r 392.409, crystals, *mp* 271.5–272.7 °C.

Synthesis: The acylation of 4-(5-methyl-3-phenylisoxazol-4-yl)benzenesulfonamide (valdecoxib), with propionic anhydride in a solution of triethanolamine (TEA) and 4-dimethylaminophenol (DMAP) in tetrahydrofuran gives *N*-[4-(5-methyl-3-phenylisoxazol-4-yl)phenylsulfonyl]propionamide, which is treated with NaOH in ethanol to give the sodium salt of parecoxib [79, 306, 307].

Clinical use: Parecoxib [77, 78, 80] is a third-generation COX-2 inhibitor. Parecoxib is a prodrug of valdecoxib with aqueous solubility sufficient for the use in parenteral formulations. The compound induced potent pain inhibition in dental, gynecological and orthopedic surgery and produced less gastrointestinal side effects than conventional COX-1 inhibitors [81].

Parecoxib is rapidly hydrolyzed in the liver to its active metabolite valdecoxib. Plasma peak concentrations for valdecoxib are achieved within 1.1 to 3.5 and 0.27 to 2 h after i.m. and i.v. administration, respectively. The elimination half-life for parecoxib is 15 to 35 min and 5 min for i.m. and i.v. administration, respectively. Metabolism of parecoxib follows the metabolism of the active metabolite valdecoxib which is a substrate for CYP3A4 and CYP2C9.

Parecoxib was used in doses of 20 and 40 mg of its sodium salt in the short-term treatment of postoperative pain.

Parecoxib together with valdecoxib was withdrawn from the market because of an increased risk of cardiovascular side effects [312, 313].

Trade names: Dynastat, Rayzon, Xapit (compound withdrawn from EU and US markets).

Rofecoxib [*162011-90-7*], 4-[4-(methylsulfonyl)phenyl]-3-phenylfuran-2(5*H*)-one, $C_{17}H_{14}O_4S$, M_r 314.36.

Synthesis: Condensation of phenylacetic acid with ethyl bromoacetate in the presence of triethylamine in THF yields ethyl 2-(phenylacetoxy)acetate, which is cyclized to the hydroxyfuranone using potassium *tert*-butoxide in *tert*-butanol. The reaction with trifluorosulfonyl anhydride and diisopropylethylamine in CH_2Cl_2 affords the corresponding trifluorosulfonate, which by reaction with LiBr in hot acetone yields the bromofuranone. The coupling with 4-(methylsulfanyl)phenylboronic acid with Na_2CO_3 and $Pd[(C_6H_5)_3P]_4$ as catalysts in hot toluene gives 4-[4-(methylsulfanyl)phenyl]-3-phenylfuran-2(5*H*)-one, which is finally oxi-

dized with $2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$ (oxone) [314].

Rofecoxib can also synthesized by several different routes [156]. In 2001 a highly efficient synthesis of rofecoxib was described [316]. As illustrated in the following scheme, the acetophenone (**i**) is prepared according to the literature by Friedel–Crafts acylation with thioanisole. Oxidation with magnesium monoperoxyphthalate hexahydrate (MMPP) affords the sulfone (**ii**), which is reacted with bromine in chloroform in the presence of a trace amount of $AlCl_3$ to give (**iii**). Bromoketone (**iii**) is then coupled and cyclized in a second step, in a one-pot procedure with phenylacetic acid. The mixture of bromoacetophenone (**iii**) and phenylacetic acid in acetonitrile was then treated with triethylamine at room temperature to provide the ester intermediate, subsequent cooling and addition of dibutylurea (DBU) effected the cyclization to provide rofecoxib as the final product.

Clinical use: Rofecoxib [156, 317, 318] is a second-generation selective COX-2 inhibitor. It was the second COX-2 selective drug to reach the market in 1999. The selectivity for COX-2 compared to COX-1 is more than 800-fold in cellular assays and more than 10-fold in whole blood assays [319].

Rofecoxib is used for treatment of rheumatoid arthritis, osteoarthritis (12.5–25 mg/d) and pain of different origin such as postoperative pain, dental pain, and primary dysmenorrhoea (50 mg/d).

Rofecoxib reaches peak plasma concentrations between 2 to 9 h after oral administration. It is bound about 87 % to plasma protein and has an elimination half-life of about 17 h. Therefore a once daily dosing is appropriate. The main metabolites formed in the liver are the *cis*-dihydro and *trans*-dihydro derivatives of rofecoxib. Rofecoxib is excreted in the form of its metabolites mainly in the urine (72 %) with some unchanged drug excreted in the feces (14 %).

Rofecoxib shows significantly less gastrointestinal toxicity than ibuprofen in studies with osteoarthritis patients [320] and compared to naproxen in patients with rheumatoid arthritis [321]. Rofecoxib does not prolong bleeding time.

Rofecoxib was withdrawn from the market at the end of 2004 after it had been shown that use for a period of more than 18 month increased

the risk of heart attack and stroke [31]. It is being discussed with the health authorities that a relaunch should be possible under appropriate safety regulations [322].

Trade name: Vioxx (EU, USA; currently withdrawn from the market).

Valdecoxib [*181695-72-7*], 4-(5-methyl-3-phenylisoxazol-4-yl)benzenesulfonamide, $C_{16}H_{14}N_2O_3S$, M_r 314.366; *mp* 172-173 °C.

Synthesis: Deoxybenzoin is converted to the corresponding oxime by treatment with hydroxylamine under basic conditions with sodium acetate in aqueous ethanol or in toluene in presence of potassium hydroxide in absolute ethanol. The treatment of the oxime under nitrogen with two equivalents of butyllithium in tetrahydrofuran is followed by cyclization in ethyl acetate or acetic anhydride to the isoxazoline derivative. Finally, treatment of the isoxazoline with cold chlorosulfuric acid followed by reaction of the intermediate with aqueous ammonia affords the desired product [79–81, 156, 316, 323].

Clinical use: Valdecoxib [79, 324–326] is a third-generation COX-2 inhibitor. It shows about 30-fold selectivity for COX-2 in a whole-blood assay. The compound has a very low solubility in water and can only be administered orally. For parenteral administration, a water-soluble prodrug derivative, parecoxib, was developed in parallel. Valdecoxib showed strong analgesic and anti-inflammatory properties and was developed for the treatment of osteoarthritis, rheumatoid arthritis [327] and acute and chronic pain of various origin [328] including migraine headache [329].

Valdecoxib is converted in rodents and dogs, and in a low abundance in humans, by hydroxylation of the methyl group to an active metabolite (4-(5-hydroxymethyl-3-phenylisoxazol-4-yl)benzenesulfonamide).

Valdecoxib induced severe allergic skin reactions [330, 331] which, together with an increased risk of cardiovascular side effects [332] was the reason why the compound, together with its prodrug derivative parecoxib, was withdrawn from the market in 2004.

Trade name: Bextra (EU, USA; currently withdrawn from the market).

3. Centrally Acting Analgesics

3.1. Opioids

The term "centrally acting analgesics" is used for compounds which inhibit the pain reaction predominantly within the central nervous system. Most of them induce a very powerful pain inhibition and are thus named synonymously "strong analgesics". The most important representatives of this group are the opioids [333]. In respect to structural features [334] opioids can be separated into three groups:

- The first group contains the natural products morphine, codeine, and thebaine, which are isolated from opium. The group contains in addition various semisynthetic derivatives of the three compounds, which are prepared by chemical modifications of these natural products.
- The second group encompasses fully synthetic compounds which often have a total different chemical structure than the semisynthetic analogues, but interact with the same opioid receptors and show the same spectrum of analgesia and side effects as the natural compounds. For both groups together the older name "opiates" is still in use.
- The third group consists of naturally occurring and synthetic peptides with opioid-like properties. The opioid peptides were discovered during the search for endogenous ligands of the opioid receptors and share the same action and side effect profile with the nonpeptidic compounds, but they are not in clinical use.

Opioids interact with specific receptors (receptor ligands) and they can act as pure agonists, as partial agonists (agonists with a reduced intrinsic activity) or as antagonist (binding without intrinsic activity). Only few compounds of the opioid family are selective ligands for a single type of opioid receptor (Table 3). Most of them bind with similar or different affinities to more than one receptor type and the pharmacological effect is the result of the combined effects on all receptors involved. Opioids may act as a full or partial agonist on one receptor type and as an antagonist on the other. These compounds are named mixed agonist – antagonists and they are an important subgroup of opioid analgesics (see Section 3.1.2.1). Opioid analgesics are the most important drugs for the treatment of moderate, severe, and very severe pain.

Humans and most animal species are equipped with opioid receptors and endogenous ligands. This endogenous opioid system [336] is widely distributed within the body, it is phyllogenetically very old and is expressed in all vertebrates. A high density of opioid receptors is found in the brain [337] and in the spinal cord, where it is involved in pain inhibition and additionally in many other central regulatory processes. In addition to the CNS localization, opioid receptors are expressed in many peripheral organs [338]. Of great importance are the opioid receptors of the gastrointestinal system, which regulate stomach emptying, gut motility, and intestinal fluid secretion. Opioid receptors are found in cells of the immune system and peripheral opioids seem to be involved in the regulation of inflammatory and immunological processes [339]. In addition to the outstanding role in the central pain inhibition, action at *peripheral* opioid receptors, which are expressed in high quantities during inflammation and immune stimulation, may add to central pain inhibition [340].

Opioid Receptor Types. Differences in analgesic activity and in the side effect profile of synthetic opioids reinforced speculations that more than one type of opioid receptor exists and is involved in the analgesic activity of these compounds. Martin and coworkers investigated in 1960 these differences in a specially developed test model, the chronic spinal dog [341] and postulated three types of opioid receptors, the μ-receptor (ligand = morphine), the κ-receptor (ligand= ketazocine) and the σ-receptor (ligand = SKF 100 81). This was later confirmed by binding experiments with radioactive-labeled ligands and by the different binding and action profiles of the endogenous opioid peptides, the enkephalins and endorphines [342]. Up to now, three types of receptors, the μ-, κ-, and δ-opioid receptor have been confirmed [343, 344], the σ-receptor is no longer considered to be an opioid receptor.

More recently, a fourth opioid receptor type, named opioid receptor like (ORL1) receptor has been identified [345]. The receptor was detected as a c-DNA, which coded for a protein with opioid receptor-like properties. Within a short time, the endogenous ligand, a peptide named nociceptin, was isolated, which, depending on the place and route of application, induced pronociceptive or anti-nociceptive actions. The full spectrum of biological activity of nociceptin and the physiological role of the ORL-1 opioid receptor in pain processing is still under investigation [367].

Subtypes of the Different Opioid Receptors. Corresponding to other receptor systems, binding studies and functional investigations indicate that subtypes of opioid receptors exist [346, 347]. Within the μ-receptor two subtypes, the μ-1 and μ-2 receptor have been described. It was postulated by some investigators [347] that analgesia and opioid side effects are differently distributed between μ-receptor subtypes, which should allow separation of analgesia from the unwanted opioid side effects. According to Pasternak and Wood [347], analgesia should be mediated by the μ-1 receptor site, whereas respiratory depression and addiction is mediated via the μ-2 receptor subtype. But in contrast to binding experiments, the functional separation of the μ-1 and μ-2 subtype is more equivocal and a clear separation of analgesia from respiratory depression and addiction potential had never been found within the μ-opioids. Therefore, a differentiation of μ-opioid analgesics according to subtype specificity is no longer maintained.

The subtypes of μ-opioid receptors could not be confirmed in cloning experiments [348]. Therefore, possible heterogeneity of opioid receptor subtypes must result from a later modification which is independent from the gene level.

Possible variations could include splice variants, receptor association, posttranslational modifications (e.g., glycosidation) or coupling with different transduction mechanisms.

Endogenous Opioid Peptides. For each class of opioid receptors endogenous ligands of peptidic structure exist, which show a distribution within the body corresponding to that of the receptor. Three distinct families of ligands with various members have been identified and named endorphins, enkephalins, and dynorphins (Table 2). The opioid peptides are split off in the organism from specific precursor polypeptides. Enkephalins are derived from proenkephalin and interact with μ- and δ-opioid receptors. The precursor molecule of endorphin is pro-opiomelanocortin (POMC), which additionally releases peptidic hormones such as α-MSH, ACTH and β-LPH. Endorphins are specific ligands of the μ-opioid receptor type. Dynorphins interact with the κ-opioid receptor and are derived from pro-dynorphin. ORL binding sites have recently been identified together with its endogenous peptidic ligand named nociceptin (Table 2).

Various further natural and synthetic opioid peptides, acting as agonists or antagonist at the different opioid receptors have been discovered. They have the same effect and side effect profile as their nonpeptidic counterparts. Opioid peptides are only used experimentally and no compound has reached clinical application.

Molecular Pharmacology of Opioid Receptors. The first successfully cloned opioid receptor was the δ-opioid receptor of the mouse, which was in parallel described by the groups of Kieffer [349] and Evans [350]. Both used neuroblastoma-glioma hybridoma cells which expressed a high density of δ-receptors in their membrane. The isolated receptor protein consisted of 372 amino acids and had a molecular mass of 40 644. The amino acid sequence showed a partial overlap with the receptors of somatostatin (37 %), angiotensin (31 %) and interleukine-8 (22 %). Similar to the somatostatin receptor, seven hydrophobic domains were identified by which the receptor is inserted into the lipid bilayer of the cell membrane. Shortly thereafter the rat and human δ-receptors were cloned. With the same technique a novel opioid-like cDNA was isolated [351], which coded for an unknown opioid receptor. The new receptor had many similarities with the classical opioid receptors [352] and was added as the forth member to the opioid receptor family under the name ORL-1. All four opioid receptors have been identified in humans. All together, they show a high degree of structural identity, which corresponds to their widely overlapping biological functions [348, 353].

All opioid receptors belong to the group of pertussis toxin sensitive G-protein-coupled receptors of the rhodopsin family with seven transmembrane spanning hydrophobic domains. The N-terminal part is oriented to the outer side of the cell membrane and is involved in the selection and binding of the receptor specific ligands. Studies with chimeric or point mutated receptors indicate that predominantly the second and third extracellular loop determines receptor selectivity. The N-terminal sequence contains several free amino groups which can be conjugated with sugar residues. The carboxy-terminal is directed into the inner part of the cell and is involved in the signal transduction cascade. The carboxy-terminal contains groups which can be phosphorylated and which are involved in receptor internalization and inactivation. The seven transmembrane regions are connected by extracellular and intracellular loop regions of different length. Comparing the sequence of the μ-, δ-, and κ-receptor reveals that the highest degree of similarity is located in the transmembrane regions and in the intracellular loop, whereas the external loops and both terminal regions are more heterogeneous. The external loops and the terminal part are involved in the selection and binding of the ligands and contain the structural elements, which determine the receptor selectivity.

Transduction Mechanisms of Opioid Receptor Interaction. As described above, all four receptor types belong to the group of G-protein-coupled receptors (GPCRs) [354]. Agonistic binding at the receptor induces association of the α-, β-, and γ- subunit of the G-protein which triggers several biochemical reactions within the cell [355–358]. Most important for the pharmacological effects of the opioids are:

Table 2. Mammalian endogenous opioid peptides

Precursor	Endogenous peptide	Amino acid sequence
Pro-opiomelanocortin	β-endorphin	YGGFMTSEKSQTPLVTLFKNAIIKNAYKKGE
Pro-enkephalin	[MET]enkephalin	YGGFM
	[LEU]enkephalin	YGGFL
Pro-dynorphin	dynorphin A	YGGFLRRIRPKLKWDNQ
	dynorphin B	YGGFLRRQFKVVT
	α-neoendorphin	YGGFLRKYPK
	β-neoendorphin	YGGFLRKYP
Pro-nociceptin/OFQ [a]	Nociceptin	FGGFTGARKSARKLANQ

[a] OFQ = orphanin FQ.

- Activation of a hyperpolarizing K^+ channel (inward rectifying K^+ channel)
- Inactivation of voltage-dependent Ca^{2+} channels (N-, P- and R-type)
- Inhibition of adenylate cyclase

A further relevant mechanism involved in the inhibition of synaptic transmission by opioids is a direct impairment of the exocytotic release of neurotransmitters, induced by stabilization of the presynaptic membrane.

Additional actions with only partially understood relevance are activation of phospholipases (PLH2, PLC7), activation of MAP kinases and activation of some voltage dependent Ca^{2+} channels (L-type and T-type).

As a result of these actions opioids inhibit neurotransmission at the presynaptic and postsynaptic site. The presynaptic inhibition mostly depends on the direct inhibitory effect on transmitter exocytosis from membrane-associated storage vessels. This direct effect is increased by the inhibition of Ca^{2+} channels, since Ca^{2+} ions trigger the transmitter release. Activation of K^+ ions induces membrane hyperpolarization and this is the most important action component for postsynaptic inhibition.

Activation of K^+ channels, inactivation of Ca^{2+} channels and direct inhibition of neurotransmitter release are powerful mechanisms by which opioids inhibit the neuronal transmission of the pain signal.

Opioid receptors are not only located at excitatory synapses, but are likewise expressed at inhibitory neurons. At these synapses, opioids inhibit the transmission of the inhibitory signal, and this inhibition of inhibition as the result, induces excitation and an increased release of neurotransmitters in the innervated neuron.This explains why opioids, in addition to their prominent inhibitory actions, have some stimulant effects, too.

Relation of the Biological Effect to the Opioid Receptor Type. The peptide structure of the four different opioid receptors is very similar [348] and this is the reason why most of the opioid receptor ligands show affinity for more than one type of receptor. In most cases, one type is preferred and the action and side effect profile is dominated by the properties of this receptor. A huge chemical effort was necessary to develop receptor-specific "selective" ligands, but nowadays several selective agonists and antagonists for each type of opioid receptor exist (Table 3).

μ-Opioid Receptors. Binding experiments and investigations in pain models have shown that predominantly the μ-receptor and to a lesser degree the κ-and d-receptors mediate pain inhibition. Most of the clinically used opioid analgesics [359] have prevalence for the μ-opioid receptor and this confirms that μ-receptor activation is the common pain inhibiting mechanism of these compounds. Since morphine is the prototype, they are called "morphine-like"analgesics. Their side effect profile includes respiratory depression, constipation as well as addiction and dependence. All these effects, corresponding to analgesia, are mediated via μ-opioid receptor activation. This is the reason why the primary goal of the development of synthetic opioids, the separation of analgesia from the addiction and dependence potential, has never been achieved. The involvement of the same receptor population in analgesia and side effect profile of morphine and morphine-like opioids was impressively confirmed in μ-knockout mice [360,

Table 3. Opioid receptor specifity

Receptor type	Selective ligands		Nonselective ligands	
	Agonist	Antagonist	Agonist	Antagonist
MOR	morphine	CTOP	levorphanol	naloxone
μ-	fentanyl		etorphine	naltrexone
	methadone			
	DAMGO			
KOR	enadoline	nor-BNI	levorphanol	naloxone
κ-	U50,488		etorphine	naltrexone
	dynorphin			
DOR	DPDPE	naltrindol	levorphanol	naloxone
δ-	SNC-80		etorphine	naltrexone

MOR = mu-opioid receptor. KOR = kappa-opioid receptor. DOR = delta-opioid receptor. DAMGO = [D-Ala^2, MePhe^4, Gly(ol)^5]enkephalin. Enadoline = (5*R*)-(5α,7α,8β-(-)-*N*-methyl-*N*-(7-[1-pyrrolidinyl]-1-oxaspiro[4,5]*dec*-8-yl)-4-benzofuranacetamide, previously CI977. U50,488 = *trans*-3,4-dichloro-*N*-methyl-*N*-[2-(1-pyrrolidinyl)-cyclohexyl]-benzeneacetamide methanesulfonate. DPDPE = [D-Pen^2, D-Pen^5]enkephalin. SNC-80 = (+)-4-[(α*R*)-α-((2*S*,5*R*)-4-allyl-2,5-dimethyl-1-piperazinyl)-3-methoxybenzyl]-*N*,*N*-diethylbenzamide. CTOP = D-Phe-Cys-Tyr-D-Trp-Orn-Thr-Pen-Thr-NH_2. nor-BNI = nor-binaltorphimine.

361]. In these animals, morphine did neither show an analgesic effect nor side effects. There was no respiratory depression and no inhibition of gastrointestinal motility and secretion. In behavioral models in μ-knockouts, morphine did not induce liking or any other signs of addiction and repeated treatment with morphine did not produce signs of tolerance and physical dependence.

***κ**-Opioid Receptors.* Activation of κ-receptors induces a clinically relevant pain inhibition [362, 363], which seems to be less efficacious than μ-receptor mediated analgesia. κ-Receptor interaction is a common action component of the so-called partial opioid agonists or agonists – antagonists, such as pentazocine, nalbuphine, and butorphanol (see Section 3.1.1.1). The most prominent side effects of κ-activation are sedation and diuresis. In contrast to μ-agonists, which induce well-being and euphoria, activation of κ-receptors in the limbic system induces dysphoria and other unpleasant psychic effects, such as hallucinations and spatial disorientation. The dose range of analgesia and psychic side effects partly overlap and this interferes with the medical use of κ-receptor agonists. In compounds with a marked κ-agonistic component (cyclazocine, nalorphine) the dysphoric side effects are so prominent that the compounds could not be used for therapeutic purposes. This may explain why despite an intensive search for κ-selective analgesics, no selective κ-agonist has ever reached the clinical use.

***δ**-Opioid Receptors.* In contrast to μ- and κ-receptors, indications for a prominent role of δ-receptors in the pain process are less obvious [364, 365]. There is a broad but still controversial discussion concerning a genuine analgesic effect mediated by δ-1 or δ-2 receptors, because analgesia is scarcely observed in compounds with pure δ-agonistic activity.

ORL-1 Receptors. The ORL-1 receptor [352, 366] differs in its peptide sequence from the classical opioid receptors. In contrast to these, ORL-1 receptor activation at least at the supraspinal level has a pronociceptive effect and induces pain. Supraspinally induced release of spinal CCK-8, NMDA or PGE-2 is discussed as the mechanism of pronociceptive activity. Spinal application of nociceptine incontrary induces anti-nociception. With the aid of nonpeptidic ORL-1 agonists and antagonists, which are currently under development, it will be possible to elucidate the contribution of the ORL-1 opioid system to pain processing and to other physiological processes [367].

Location of Opioid Receptors in the Pain Pathway. The endogenous opioid system [368] is the most important component of the pain inhibitory system of the body. Opioids act at different levels of the pain pathway and their action interferes with different aspects of the pain processing [369, 370].

Opioids induce:

- Inhibition of the transmission of the pain signal

- Inhibition of the emotional aspect of pain
- Inhibition of pain realization

Pain processing is inhibited at the spinal and supraspinal level. Spinal opioid receptors are located pre- and postsynaptically at interneurons of the *substantia gelatinosa* of the dorsal horn. The opioid interneurons inhibit the release of excitatory transmitters and reduce the transmission of the pain signal from the primary afferents to the secondary neurons of the spinal ascending pain pathway. Supraspinally, opioids are located in different regions of the brainstem, in the periaquaeductal grey matter, in the limbic system, in the thalamic nuclei, in the basal ganglia, and in the cortex. Cortical and thalamic localization is involved in the perception of the pain stimulus, cortical regions in addition in the localization of the origin of the pain focus.

Opioids in the different parts of the limbic system suppress the emotional component of pain and the pain suffering. In the *formatio reticularis*, they inhibit the pain induced activation of autonomous functions, such as increase in respiration, increase in blood pressure and sweating. Inhibitory actions at the *formatio reticularis* are the origin of the most prominent side effects of the opioids, like respiratory depression, bradycardia and the centrally mediated part of the gastrointestinal inhibition.

In addition to the inhibitory effect at the ascending pain transmission, opioids activate a descending pain inhibitory system, which originates from different centers of the pons and medulla, such as *nucleus coeruleus*, areas of the periaquaeductal grey matter, and areas of the raphe nuclei. The descending nerve fibers terminate at the spinal interneurons in noradrenergic and serotoninergic inhibitory synapses, which suppress the ascending pain signal. Thus, opioids inhibit the spinal pain processing by two mechanisms, one is a direct pre- and postsynaptic inhibition of the ascending pain pathway and the other is a centrally-mediated activation of the descending pain inhibitory system.

Use of Opioids in Pain Treatment. Opioids are used for the treatment of moderate to severe or very severe pain of acute or chronic type [371]. Nearly all forms of pain are sensitive to opioid treatment and in contrast to traditional opinions even neuropathic pain is reasonably sensitive to higher doses of opioids. This was clearly shown in well-controlled clinical studies [372]. The most important use of opioids in acute pain treatment is postoperative pain, whereas treatment of cancer pain, often accompanied by a neuropathic pain component, is the classical domain of *chronic* opioid treatment.

Opioid Side Effects.

Respiratory Depression. Opioids induce respiratory depression via inhibition of the respiratory center of the *medulla oblongata*, which respond to the pCO_2 content of the blood [373, 374]. The inhibitory effect is more prominent in respect to the respiratory frequency than to the volume of respiration. At higher opioid dosages, respiration becomes irregular and grasping occurs. In awake persons, respiratory depression by opioids can be voluntarily compensated over a broad dose range. Respiratory impairment is not a prominent feature in awake pain patients, because pain itself is a strong stimulus for respiration.

Opioid-induced respiratory depression is augmented by other CNS-depressant compounds such as sedatives and hypnotics. Respiratory depression becomes an important side effect when opioids are used for postoperative pain treatment, because the anesthetic agent and most adjuncts of anesthesia induce a long lasting depressant effect on respiration, which can increase the opioid effects up to respiratory arrest. Therefore a careful supervision of respiration during the postoperative period is mandatory [375]. Opioid-induced respiratory depression can be interrupted by the opioid antagonist naloxone. Naloxone has a short duration of action and repeated applications may be necessary to successfully counteract the effect of longer acting opioids. Highly potent opioids induce severe respiratory depression in the higher dose range. In addition, they induce a stiffness of the chest musculature [376], called chest rigidity or "wooden chest", which is mediated via stimulation of dopamine release in the *nucleus caudatus*. Chest rigidity further increases the respiration impairment by these compounds. Therefore higher doses of potent opioids such as fentanyl and analogues, as used for anesthesia, need artificial or at least assisted ventilation.

Cardiovascular Effects. Nearly all opioids induce bradycardia [377], most likely mediated

via central stimulation of the vagus nerve. The cardiovascular depression of most opioids is moderate and only the stronger opioids of the fentanyl group induce a more prominent effect. Morphine and some analogues induce a non-opioid receptor mediated release of histamine, which can result in a decrease in blood pressure and a compensatory tachycardia.

Gastrointestinal Effects. Opioids induce an inhibitory effect on gastrointestinal motility and fluid secretion [378]. The effect is peripherally and centrally mediated. The peripheral part is related to μ- and κ-receptors at intestinal organs, which are densely equipped with opioid receptors. The receptors are located at parasympathic ganglions and inhibit the release of acetylcholine, which stimulates the contraction of the smooth muscles. Inhibition of the intestinal fluid secretion is mediated via inhibition of adenylate cyclase. The intestinal effects of opioids extend to all parts of the gut and results in inhibition of stomach emptying and inhibition of secretion and motility in the duodenum, jejunum, colon, and rectum.

Reduced motility and secretion can let to constipation, which is the most prominent side effect of chronic opioid treatment [379]. Opioid-induced constipation can increase up to megacolon or paralytic ileus. Therefore chronic opioid treatment should be accompanied by concomitant use of laxatives. Besides their peripheral actions, opioids are involved in the **central** regulation of intestinal functions which is located in the *formatio reticularis*. This explains why the intestinal side effects of opioids are not restricted to the more hydrophilic compounds such as morphine, but are seen likewise in the more centrally active lipophilic analogues. During chronic opioid treatment a varying degree of tolerance towards the intestinal side effects may occur.

The intestinal inhibitory action of opioids can be used for the treatment of diarrhea [380]. The clinically most important antidiarrheal opioid is loperamide [381]. After oral administration, loperamide acts locally within the gastrointestinal tract. After parenteral administration, the compound is rapidly inactivated and does not reach the CNS. Therefore loperamide does not show the typical central opioid side effects, has no analgesic action and has no abuse potential.

Emetic Activity. Nausea and emesis are common unpleasant side effects of opioids [382, 383]. They are most intensively experienced at the beginning of the treatment. During chronic application, tolerance may occur, which reduces the emetic sequelae. Nausea and emesis are induced via activation of chemoreceptors, which are located in the trigger zone of the area postrema of the *formatio reticularis.* The receptors are located at the tissue surface and contact the circulating blood. Thus the emetic effect of opioids is not mediated centrally, which means after penetration of the blood – brain barrier, but rather peripherally via the part of the compound, which is distributed in the circulating blood.

After passage through the blood – brain barrier, opioids have an antiemetic effect [384]. The emesis inhibition is induced via blockade of an emesis center located in a more central area of the *formatio reticularis*. This explains why the emetic effect of opioids is most prominent immediately after application, especially after rapid intravenous administration and is reduced or terminated when the compound has reached the CNS. The more hydrophilic opioids such as morphine have stronger emetic side effects than lipophilic compounds like methadone or fentanyl [385], which are rapidly transported into the CNS.

Tolerance and Dependence. μ-Opioid compounds induce a feeling of well being and euphoria, which is mediated by the release of dopamine within the limbic system. κ-Opioids induce an opposite effect with dysphoria, disorientation, and hallucinations [386]. Repeated activation of the μ-opioid rewarding system may induce a psychological dependence, which leads to addiction and a compulsory behavior of drug seeking [387]. In addition, higher opioid dosages, as used for nonmedicinal purposes, induces tolerance and as a consequence a further increase of the dose to achieve the intended effect. In the course of the tolerance development opioid users becomes physically dependent on the supply of the compound [388] and suspension of the treatment or blocking of the opioid receptors with an antagonist induces a withdrawal reaction, characterized by strong dysphoria, restlessness, pain, and various symptoms of autonomic dysregulation, like diarrhea, shivering, chills and cardiovascular collapse.

The euphorigenic effect of opioids, the "opioid kick", is more intensely induced by lipophilic compounds such as diacetylmorphine (heroin), which rapidly penetrates into the CNS. The feeling of euphoria on the one hand and the absence of well-being on the other hand is more prominent when brain concentrations of the opioid change rapidly. This intensifies drug seeking behavior and psychological as well as physical dependence.

In contrast to recreational use, chronic pain treatment with opioids afforts constant dosing and has only a limited risk to induce psychological dependence and drug addiction [389]. A proper dosing during chronic pain treatment can often postpone tolerance development for longer time periods. The most important precaution to avoid tolerance and dependence development is to ensure constant plasma levels of the opioid, which have to be high enough to give complete pain relief. This can be reasonably achieved by oral administration of retarded formulations or by an opioid patch [390]. Breakthrough pain, which is often induced by a fluctuation in pain intensity, should be rapidly compensated by additional treatment with an immediate release formulation of the same or a similar opioid.

3.1.1. Opioids in Clinical Use

3.1.1.1. Morphine and Morphinane Derivatives

Morphine [*57-27-2*], (5α,6α)-7,8-didehydro-4,5-epoxy-17-methylmorphinan-3,6-diol, $C_{17}H_{19}NO_3$, M_r 285.34, *mp* 254 °C (decomp., 197 °C is reported for a metastable phase), $[\alpha]_D^{25}$ $-132°$ (c = 1, CH_3OH); hydrochloride [*52-26-6*], $C_{17}H_{19}NO_3 \cdot HCl$, M_r 321.80, *mp* 200 °C (trihydrate), $[\alpha]_D^{25}$ $-113.5°$ (c = 2.2, water); sulfate (2 : 1) [*64-31-3*], $C_{17}H_{19}NO_3 \cdot 1/2\ H_2SO_4$, M_r 668.76; sulfate pentahydrate [*6211-15-0*], $C_{17}H_{19}NO_3 \cdot 1/2\ H_2SO_4 \cdot 5H_2O$, M_r 758.85, *mp* 250 °C (decomp.), $[\alpha]_D^{25}$ $-108.7°$ ($c = 4$, water). Morphine is the main alkaloid of opium, isolated from the milky liquid of the poppy seed capsule [108].

Preparation: Morphine is obtained by extraction of poppy capsules or opium (opium contains 9–14 % morphine, depending on the source) with water, precipitation with aqueous Na_2CO_3-solution, washing of the precipitate with ethanol and dissolving in diluted acetic acid [392–395].

Morphine in the conventional presentation (left) and in a stereoformula according to IUPAC rules (right)

The total synthesis of (-)-morphine had been a challenging target for organic chemists for many decades [316, 334, 396]. Although a number of successful syntheses were developed, only a few could produce the compound in an enantio- and diastereo-controlled manner [397–399].

Morphine biosynthesis: The studies on the biosynthesis of morphine have been performed on cell cultures mainly of *Coptis japonica* and species of *Thalictrum*. The overall biosynthetic pathway from tyrosine to morphine is depicted in Figure 3.

Opioid receptor binding: Morphine has a high (nanomolar) binding affinity for the μ-opioid receptor. The affinity for the δ- and κ-opioid receptor is at least 10-fold lower.

Clinical use: Morphine is a very potent analgesic and still the "gold standard" for the treatment of severe, acute, and chronic pain [400]. The compound is used in various salt forms, preferentially as the hydrochloride or sulfate. Morphine can be administered orally or parenterally. Oral administration is preferred for chronic pain treatment and various slow-release forms have been developed to reduce the application frequency to 1–2 times per day. Parenterally, morphine is used in doses of 10 mg mostly for postoperative pain and self-administration devices have been developed for patient-controlled analgesia (PCA).

Other morphine preparations are under evaluation for local administration, e.g., inhalation via the broncho-pulmonal way.

Pharmacokinetic properties: Morphine is extensively metabolized by glucuronidation at both hydroxyl groups at positions 3 and 6 and by *N*-demethylation [401, 402]. The 3-glucuronide has a minimal opioid receptor binding affinity

Figure 3. The overall biosynthetic pathway from tyrosine to morphine

and is devoid of analgesic action, whereas the morphine-6-glucuronide has a similar binding affinity as morphine, is analgesically active and seems to be involved in pain inhibition during chronic oral treatment with morphine [403]. Despite the polar sugar residue the glucuronide can pass the blood – brain-barrier. The morphine-6-glucuronide is being tested as an independent opioid analgesic. The *N*-demethyl derivative normorphine is analgesically active, but has a lower μ-receptor affinity, a lower potency and a shorter duration of action than morphine. Normorphine is not in clinical use.

The main metabolites of morphine are shown in Figure 4.

Figure 4. Metabolic pathway of morphine

Side effects: Morphine induces a variety of centrally and peripherally mediated side effects. Most important after parenteral administration is respiratory depression, especially in the postoperative situation. Chronic oral administration induces constipation and chronic treatment with oral morphine has to be supplemented with laxatives. Other frequent side effects are nausea, vomiting, dizziness, and sedation.

Morphine is a controlled substance. It has a high euphorigenic potential and is liable to abuse and dependence. The euphorigenic effect is less expressed in the context of pain treatment and tolerance and dependence can largely be avoided by appropriate dosing and application intervals, securing constant and pain-appropriate plasma levels of the compound.

Trade names: M-Long (Germany), MST continuous (Germany, UK), Capros (Germany), Kapanol (Germany, USA), Moscontin (France), Infumorph (USA), Oxamorph (USA).

Morphine is also marketed in many generic formulations.

Codeine [*76-57-3*], $C_{18}H_{21}NO_3$, M_r 299.36, *mp* 154–156 °C (monohydrate from water or diluted alcohol), anhydrous form sublimes at 140–145 °C and 133.32 Pa, $[\alpha]_D^{25}$ −136° (c = 2, CH_3CH_2OH); monohydrate [*6059-47-8*], $C_{18}H_{21}NO_3 \cdot H_2O$, M_r 317.38, *mp* 154–156 °C; hydrochloride dihydrate $C_{18}H_{21}NO_3 \cdot HCl \cdot 2\ H_2O$, M_r 371.86, *mp* 280 °C (decomp.), $[\alpha]_D$ − 108°; hydrobromide dihydrate [*125-25-7*], $C_{18}H_{21}NO_3 \cdot HBr \cdot 2\ H_2O$, M_r 416.31, *mp* 190–192 °C (anhydrous), $[\alpha]_D$ − 96.6°; phosphate [*52-28-8*].

Preparation: Codeine is extracted from opium (concentration in opium 0.7 to 2.5 %, depending on the source), but mostly prepared by methylation of morphine in a phase transfer reaction [404, 405].

Opioid receptor binding: Codeine has a low affinity at μ-, δ-, and κ-opioid receptors and the in vivo effects are predominantly induced by metabolization to morphine [55].

Clinical use: Codeine [407] is an O-methyl analogue of morphine. It has a morphine-like action profile but a 5–10 times lower potency. Codeine has a good oral availability and oral administration forms are used for the treatment of mild to moderate pain and as antitussive (→ Cough Remedies, Section 2.1.1). In therapeutic dosages, codeine produces fewer opioid-type side effects than morphine and has only a low risk of abuse. The lower abuse and dependence can be explained by the fact that the opioid action is only available after metabolic activation. High codeine doses can induce excitement and convulsions.

The compound is extensively metabolized by *O*- and *N*-demethylation followed by glucuronidation. The main metabolites are norcodeine, morphine, and hydrocodeine and their glucuronides. There are indications [408] that the analgesic effect is reduced in poor metabolizers with a low CYP2D6 activity.

Codeine is used in the form of different salts like hydrochloride, phosphate and sulfate. To increase the duration of action, slow-release preparations have been developed. Codeine salts are frequently combined with non-opioid analgesics such as paracetamol, acetylsalicylic acid, or diclofenac.

Trade names: Codipront (Germany), Codicaps (Germany), Codimal (USA).

Combination with paracetamol: Co-Tylenol (USA).

Combination with Diclofenac: Combaren (USA).

Codeine is also marketed in many generic formulations.

Ethylmorphine [*76-58-4*], (5α,6α)-7,8-didehydro-4,5-epoxy-3-ethoxy-17-methylmorphinan-6-ol, $C_{19}H_{23}NO_3$, M_r 313.40, *mp* 199–201 °C; hydrochloride dihydrate [*6746-59-4*], $C_{19}H_{23}NO_3 \cdot HCl \cdot H_2O$ M_r 385.89, *mp* 123 °C (decomp.), anhydrous form melts at 170 °C (decomp.).

Synthesis: Ethylmorphine is synthesized by ethylation of morphine with ethyl benzenesulfonate [48, 409, 410].

Ethylmorphine

Clinical use: Ethylmorphine (→ Cough Remedies, Section 2.1.1) is the ethyl congener of codeine and has a similar therapeutic application. It has a low opioid receptor affinity and is metabolized to the active metabolites morphine and normorphine. Ethylmorphine can be used as cough suppressant, medium-potent analgesic, and anti-diarrheal agent. Today the compound is widely out of therapeutic use, but is often used as clinical reagent to characterize the metabolic N-dealkylation activity of CYP3A4 [411, 412].

Trade names: Codethyline (Belgium), Trachyl (France), Collins Elixir (UK).

Diacetylmorphine [*561-27-2*], diamorphine, heroin, $C_{21}H_{23}NO_5$, M_r 369.41, *mp* 173 °C, $[\alpha]_D^{25}$ −166° (c = 1.49, CH_3OH); hydrochloride monohydrate [*561-27-2*], $C_{21}H_{23}NO_5 \cdot HCl \cdot H_2O$, M_r 423.89, *mp* 243–244 °C, $[\alpha]_D^{25}$ −156° (c = 1.044).

Synthesis: Diamorphine is prepared by acetylation of morphine with acetic anhydride [413].

Diacetylmorphine

Opioid receptor binding: Diamorphine [414] has a 10- to 100-fold lower μ-opioid receptor binding affinity than morphine. The relevant opioid properties originate from the high μ-receptor

affinity of the metabolites 6-acetylmorphine and morphine [415].

Clinical use: Diamorphine [416] is a lipophilic morphine derivative which rapidly penetrates into the central nervous system, where 6-acetylmorphine and morphine are released [417, 418]. The rapid brain access induces an immediate onset of action and this seems to be the reason for the strong euphorigenic effect and the high abuse potential. Because of the widespread abuse, therapeutic application is prohibited in many countries including Germany and the US. In other countries like the UK, parenteral heroin is used for the relief of severe pain, especially in terminal illness. The compound is more potent than morphine, but has a similar action and opioid side effect profile.

Trade name: Diagesil (UK).

Dihydrocodeine [*125-28-0*], (5α,6α)-4,5-epoxy-3-methoxy-17-methylmorphinan-6-ol, $C_{18}H_{23}NO_3$, M_r 301.38, *mp* 112–113 °C; tartrate (1 : 1) [*5965-13-9*], $C_{18}H_{23}NO_3 \cdot C_4H_6O_6$, M_r 451.47, *mp* 192–193 °C (commercial medicinal grade usually melts at 186–190 °C, $[\alpha]_D^{25}$ −72° to −75° (*c* = 1.0, water).

Synthesis: Hydrogenation of codeine yields dihydrocodeine [48, 419, 420].

Dihydrocodeine

Opioid receptor binding: Dihydrocodeine has a low μ-opioid receptor binding affinity and opioid properties are mostly due to metabolic activation to the demethyl derivative dihydromorphine.

Clinical use: Dihydrocodeine has codeine-like analgesic and antitussive properties and is used for the treatment of moderate to severe pain [421] and as antitussive [422] (→ Cough Remedies, Section 2.1.1). Dihydrocodeine is mostly used as oral immediate- or sustained-release formulations [423]. For pain treatment the dose range is 30–80 mg, for cough inhibition doses are in the range of 10 mg.

Dihydrocodeine induces morphine-like side effects, but the intensity is less pronounced. Chronic treatment may produce dependence, and abuse by opioid addicts has been reported.

Trade names: Paracodin (Germany), Dicodin (France), DHC Continus (UK), Synalgos (USA).

Etorphine [*14521-96-1*], [5α,7α(*R*)]-4,5-epoxy-3-hydroxy-6-methoxy-α,17-dimethyl-α-propyl-6,14-ethenomorphinan-7-methanol, $C_{25}H_{33}NO_4$, M_r 411.53, *mp* 214–217 °C; hydrochloride [*13764-49-3*], $C_{25}H_{33}NO_4 \cdot HCl$, M_r 447.99, *mp* 266–267 °C.

Synthesis: Starting from thebaine etorphine can be synthesized in a similar way as buprenorphine (see page 66) [424–427].

Opioid receptor binding: Etorphine [428] has a high affinity and selectivity for the μ-opioid receptor.

Clinical use: Etorphine [429] is an extremely strong and rapid-acting μ-opioid with a potency 400–1000-fold higher than morphine. The compound is very rapidly absorbed through skin and mucosa and extraordinary care is necessary to avoid contamination during medical use. Naloxone or diprenorphine can be used as antagonist. Etorphine induces strong central nervous depression and is mostly used in veterinary practice for immobilization or pain treatment of big animals [430]. Etorphine is only used parenterally.

Trade name: Immobilon (UK).

Hydrocodone [*76-42-6*], (5α)-4,5-epoxy-3-methoxy-17-methylmorphinan-6-one,

$C_{18}H_{21}NO_3$, M_r 299.36, *mp* 198 °C; hydrochloride [*25968-91-6*], $C_{18}H_{21}NO_3 \cdot HCl$, M_r 335.83; hydrochloride monohydrate [*124-90-3*], $C_{18}H_{21}NO_3 \cdot HCl \cdot H_2O$, M_r 353.85, *mp* 185–186 °C (decomp.), $[\alpha]_D^{27}$ −130° (*c* = 2.877); bitartrate hemipentahydrate [*34195-34-1*], $C_{18}H_{21}NO_3 \cdot C_4H_6O_6 \cdot 5/2\ H_2O$, M_r 494.5, *mp* 118–128 °C.

Synthesis: Palladium or platinum catalyzed isomerization of codeine yields hydrocodone [48, 431, 432].

Hydrocodone

Opioid receptor binding: Hydrocodone has a μ-opioid receptor binding affinity that is 10- to 100-fold higher than that of codeine [433]. In contrast to codeine, the compound itself has a relevant μ-opioid receptor affinity and is, in addition to the active metabolite hydromorphone, responsible for analgesia and other opioid properties.

Clinical use: Hydrocodone [420] is an opioid related to codeine with analgesic and marked antitussive properties. The compound is more potent than codeine and is used in oral doses of 5 to 10 mg for the treatment of moderate to moderately severe pain. Combinations with paracetamol or other COX inhibitors are common, as well as multi-ingredient preparations as antitussives. Hydrocodone induces side effects similar to codeine and morphine and has an appreciable abuse and dependence potential [434].

Trade names: Dicodid (Germany, UK), Vicodin (USA).

Combination with paracetamol: Zydone (USA), combination with ibuprofen: Vicoprofen (USA).

Hydromorphone [*466-99-9*], (5α)-4,5-epoxy-3-hydroxy-17-methylmorphinan-6-one, $C_{17}H_{19}NO_3$, M_r 285.34, *mp* 266–267 °C; monohydrochloride [*71-68-1*], $C_{17}H_{19}NO_3 \cdot HCl$, M_r 321.80.

Synthesis [48, 435, 436]:

Morphine is hydrogenated over a palladium catalyst, and the resulting dihydromorphine is oxidized with benzophenone and potassium *tert*-butoxide. Alternative oxidants are cyclohexanone with aluminum tri(*tert*-butoxide) or aluminum triphenoxide.

Opioid receptor binding: Hydromorphone has a high affinity and selectivity for the μ-opioid receptor, the μ-affinity is about 10-fold higher as compared to morphine.

Clinical use: Hydromorphone [437] is a morphine derivative with an analgesic potency higher than morphine. It is used as hydrochloride parenterally or orally in the dose range of 2–4 mg to treat moderate to severe pain [438] or as a syrup for cough inhibition. Hydromorphone shows the typical morphine-like side effect profile and has a relatively high potential for addiction and dependence [439].

Trade name: Dilaudid (Germany, UK, USA), Palladone (USA).

Levorphanol [*77-07-6*], 17-methylmorphinan-3-ol, (−)-3-hydroxy-*N*-methylmorphinan, $C_{17}H_{23}NO$, M_r 425.48, *mp* 198–199 °C, $[\alpha]_D^{20}$ −56° (*c* = 3, CH_3CH_2OH); tartrate dihydrate [*5985-38-6*], $C_{17}H_{23}NO \cdot C_4H_6O_6 \cdot 2\ H_2O$, M_r 257.37, *mp* 113–115 °C (anhydrous *mp* 206–208 °C), $[\alpha]_D^{20}$ −14° (*c* = 3, water).

Synthesis: The analgesic activity of racemorphan is due to the (−) isomer, levorphanol, which is obtained by resolving the racemate with (+)-D-tartaric acid. The resolution can also be performed on the intermediate 1-(4-methoxy benzyl)-1,2,3,4,5,6,7,8-octahydro isoquinoline (**1**) prior to N-methylation [48, 440–443].

Opioid receptor binding: Levorphanol is a μ-selective synthetic opioid with a higher receptor affinity than morphine [225].

Clinical use: Levorphanol [445] is a strong analgesic used as tartrate for parenteral and oral administration. Parenterally, levorphanol is 4–5 times more potent than morphine. After oral administration, the compound has a long duration of action (up to 8 h). Levorphanol has a morphine-type side effect profile with prominent respiratory depression in the high dose range. The compound induces morphine-type addiction and dependence [446].

Trade name: Levo-Dromoran (USA).

Oxycodone [*76-42-6*], (5α)-4,5-epoxy-14-hydroxy-3-methoxy-17-methylmorphinan-6-one, 14-hydroxydihydrocodeinone, dihydrone, dihydrohydroxycodeinone, $C_{18}H_{21}NO_4$, M_r 315.36, *mp* 218-220 °C; hydrochloride [*124-90-3*], $C_{18}H_{21}NO_4 \cdot HCl$, M_r 351.81, *mp* 270–272 °C (decomp.), $[\alpha]_D^{20}$ −125° (c = 2.5, water).

Synthesis [48, 447, 448]: Thebaine is oxidized with hydrogene peroxide to 14-hydroxycodeinone [449, 450], which is hydrogenated directly or via its oxime, or its bromination products to oxycodone. The reduction of 14-hydroxycodeinone can also be performed with sodium hydrosulfite. Alternatively, 14-hydroxycodeinone is prepared by oxidation of codeine (see next page, top).

Opioid receptor binding: Oxycodone [433] is a μ-selective opioid with a 10-fold higher receptor affinity than codeine. Both the parent compound and the high affinity metabolite oxymorphone mediate the opioid effects of the compound [451].

Clinical use: Oxycodone [452] is an orally active opioid analgesic for the treatment of moderate to moderately severe pain. The compound is used as hydrochloride in a dose range of 5–10 mg and is often combined with paracetamol or other COX-inhibitors. Higher dosages and oral slow-release preparations [453] are used for the control of severe pain. Oxycodone has a morphine-like side effect profile. Respiratory depression has been found in children. The compound has a relevant abuse and dependence potential and illicit use of the retarded preparations is reported. To obviate misuse, abuse deterrent formulations (ADF) and combinations with naloxone and naltrexone are under development.

Trade names: Eukodal (Germany), Eubine (France), Proladone (UK),Roxicodone, OxyContine (USA), Oxygesic (Germany)

Combination with ibuprofene: Combunox (USA).

Oxymorphone [*76-41-5*], (5α)-4,5-epoxy-3,14-hydroxy-17-methylmorphinan-6-one, dihydrohydroxymorphinone, dihydro-14-hydroxymorphinone, 14-hydroxydihydromorphinone, $C_{17}H_{19}NO_4$, M_r 301.34, *mp*

248–249 °C (decomp.); hydrochloride [*357-07-3*], $C_{17}H_{19}NO_4 \cdot HCl$, M_r 337.80.

Synthesis [454] Oxycodone is hydrolyzed with boiling concentrated hydrobromic acid.

Opioid receptor binding: Oxymorphone is a μ-selective opioid with a binding affinity in the range of morphine.

Clinical use: Oxymorphone is a synthetic morphine derivative with a potency 5–10 times higher than that of morphine. The compound is used as hydrochloride in parenteral and rectal application forms (suppositories) and as oral sustained-release formulations to treat moderate to severe pain [455]. Oxymorphone has no cough suppressant activity. Oxymorphone has a morphine-type side effect profile and can induce addiction and dependence [456].

Trade name: Numorphan (USA, Canada).

3.1.1.2. Piperidine Derivatives

3.1.1.2.1. Meperidine and Congeners

(for Diphenoxylate, Loperamide, and Piritramide see Section 3.1.1.4)

Pethidine [*57-42-1*], meperidine, ethyl 1-methyl-4-phenylpiperidine-4-carboxylate, $C_{15}H_{21}NO_2$, M_r 247.33; hydrochloride [*50-13-5*], $C_{15}H_{21}NO_2 \cdot HCl$, M_r 283.80, *mp* 186–189 °C.

Synthesis [48, 457–460]:

a) The original synthesis involved condensation of benzyl cyanide with *N*,*N*-bis(2-chloroethyl)-*N*-methyl-amine, which is a skin irritant and a carcinogen.
b) Another synthesis begins with pyridine-4-carboxylic acid.

Opioid receptor binding: Pethidine is a μ-selective synthetic opioid with an intermediate receptor affinity [461].

Clinical use: Pethidine [462] is a synthetic analgesic with μ-receptor preference similar to morphine. Pethidine, introduced in 1939, was the first fully synthetic analgesic with morphine-like activity. It has a lower potency and a shorter duration of action than morphine and is used as hydrochloride for the treatment of moderate to severe pain. It is preferentially used in parenteral formulations, perioperative and obstetrical analgesia and as adjunct to anesthesia.

Pethidine has a morphine-type side effect profile with a lower incidence of constipation. Higher doses induce central stimulation and antimuscarinic effects accompanied by pupil dilatation. In even larger doses toxic symptoms such as muscular twitching, tremor, mental confusion, and convulsions occur, which are partly attributed to the more toxic metabolite norpethidine [463]. Severe side effects including coma and cyanosis have been observed in combination with MAO-inhibitors [464]. Pethidine induces morphine-type tolerance and dependence and addicts using high doses of pethidine have an increased risk of excitatory side effects.

Due to the high risk of severe side effects the clinical use of the compound has strongly decreased [465–467].

Trade names: Dolantin (Germany), Dolosal (France), Demerol (USA).

Ketobemidone [*469-79-4*], *N*-(3-hydroxyphenyl)-*N*-(1-methylpiperidin-4-yl)-propionamide, $C_{15}H_{21}NO_2$, M_r 247.34, *mp* 150–151 °C; hydrochloride [*5965-49-1*], $C_{15}H_{21}NO_2 \cdot HCl$, M_r 283.80, *mp* 201–202 °C.

Synthesis: The cyano group of 4-cyano-4-(3-methoxyphenyl)-1-methylpiperidine is converted into a ketoethyl group by reaction with ethylmagnesium bromide. Subsequent ether cleavage by means of HBr yields ketobemidone [48, 459, 468, 469].

Ketobemidone

Opioid receptor affinity: Ketobemidone is a μ-selective synthetic opioid with a receptor affinity similar to morphine [470].

Clinical use: Ketobemidone is a synthetic opioid of the pethidine group with an analgesic potency in the range of morphine [471]. The

compound has a weak NMDA blocking effect [472], which may contribute to the analgesic efficacy. It can be given orally, by injection or rectally; usual doses are 5–10 mg. Ketobemidone has a morphine-like side effect and abuse and dependence potential [473].

Trade names: Cliradon (Germany, out of use), Ketogan (Sweden, Norway).

3.1.1.3. Fentanyl and Congeners

Fentanyl [*437-38-7*], *N*-(1-phenethylpiperidin-4-yl)-*N*-phenylpropionamide, $C_{22}H_{28}N_2O$, M_r 336.47, *mp* 83–85 °C; citrate (1 : 1) [*990-73-8*], $C_{22}H_{28}N_2O \cdot C_6H_8O_7$, M_r 528.60, *mp* 149–151 °C.

Synthesis [48, 474] (see right column).

Opioid receptor binding: Fentanyl is a μ-selective potent opioid with a similar receptor binding affinity as morphine. The higher in vivo potency of fentanyl results from its higher lipophilicity.

Clinical use: Fentanyl is a potent synthetic opioid related to pethidine [475] and has an action profile similar to morphine. Fentanyl citrate is used for the inhibition of acute and chronic severe pain, and especially as adjunct to anesthesia and as a primary anesthetic for induction and maintenance of anesthesia [476]. In combination with neuroleptics or tranquilizers it induces a surgical state named neuroleptanalgesia in which surgery can be performed in an awake, but calm and pain-free status. Fentanyl is orally bioavailable and can be administered orally (special forms exist for the oral-transmucosal route), parenterally, and transdermally as patch formulations. A formerly used less safe reservoir patch formulation has now been substituted by a new matrix patch. Fentanyl is a highly lipophilic compound and is bound to plasma proteins to about 80 %. The compound has a rapid onset and a relatively short duration of action, presumably due to tissue redistribution. The elimination half-life is longer than that of morphine.

The side effect profile is typical of potent μ-opioids with respiratory depression, increased muscle tone (chest wall rigidity during fentanyl anesthesia), strong sedation, and emesis being most prominent. Adverse reactions can be antagonized with naloxone.

Fentanyl and fentanyl derivatives (so-called designer drugs) have an essential abuse potential [477] and induce a morphine type of physical dependence.

Trade names: Actic (USA), Duragesic (USA), Durogesic, Durogesic-SMAT (Germany), Durogesic-Dtrans (UK), Fentanyl Janssen (Germany), Sublimaze (UK, USA).

Combination with Droperidol: Thalamonal.

Transdermal fentanyl patches are also marketed in generic formulations.

Fentanyl

Alfentanil [*71195-58-9*], *N*-{1-[2-(4-ethyl-5-oxo-4,5-dihydrotetrazol-1-yl)ethyl]-4-methoxymethylpiperidin-4-yl}-*N*-phenylpropionamide, $C_{21}H_{32}N_6O_3$, M_r 416,25; hydrochloride monohydrate [*70879-28-6*], $C_{21}H_{32}N_6O_3 \cdot HCl \cdot H_2O$, M_r 470.99, *mp* 138.4–140.8 °C.

Synthesis: The cyclization of ethyl isocyanate with sodium azide in the presence of $AlCl_3$ in refluxing THF gives 1-ethyl-1,4-dihydro-5*H*-tetrazol-5-one, which is alkylated with 1-chloro-2-bromoethane using Na_2CO_3 and KI in refluxing 4-methyl-2-pentanone to afford 1-ethyl-4-(2-chloroethyl)1,4-dihydro-5*H*-tetrazol-5-one (**2**) [48, 478–480].

N-(4-methoxymethyl-4-piperidinyl)-*N*-phenylpropionamide (**3**) is synthesized according the following scheme starting from 1-benzyl-4-piperidone:

Finally the tetrazole derivative **2** is condensed with the propionamide **3** in the presence of Na_2CO_3 and KI as catalysts in refluxing 4-methyl-2-pentanone.

Alfentanil

Opioid receptor binding: Alfentanil is a μ-selective opioid [481] with a receptor affinity in the range of morphine and fentanyl.

Clinical use: Alfentanil is a potent opioid analgesic with a rapid onset and a shorter duration of action than fentanyl [482]. The i. v. formulation (dose range 1–4 mg) is mainly used perioperatively as strong analgesic, supplement to general anesthesia, or as a primary anesthetic [483]. Alfentanil has a strong respiratory depressant action and high doses induce chest wall rigidity. The compound has a μ-type addiction and dependence potential.

Trade names: Rapifen (Germany, France, UK), Alfenta (USA).

Remifentanil [*132875-61-7*], methyl 1-(2-methoxycarbonylethyl)-4-(phenylpropionylamino)piperidine-4-carboxylate, methyl 4-(methoxycarbonyl)-4-[(1-oxopropyl)phenylamino]-1-piperidinepropanoate, $C_{20}H_{28}N_2O_5$, M_r 376.45; monohydrochloride [*132539-07-2*], $C_{20}H_{28}N_2O_5 \cdot HCl$, M_r 412.91; oxalate (1 : 1) [*132875-62-8*], $C_{20}H_{28}N_2O_5 \cdot C_2H_2O_4$, M_r 466.49.

Synthesis: Remifentanil is prepared by condensation of methyl 4-(phenylpropionylamino) piperidine-4-carboxylate with methyl acrylate in hot acetonitrile [48, 484–486].

Remifentanil

Clinical use: Remifentanil [487, 488] is a very short-acting and potent μ-opioid agonist with strong analgesic and anesthetic properties. It has been developed as an ultra-short anesthetic and adjunct to general anesthesia. [489, 490]. It affords potent intraoperative analgesia and has a sparing effect on concomitantly used sedatives and hypnotics [491]. Remifentanil is given as intravenous short infusion in doses of 0.5–1 μg/kg or as continuous infusions in the range of 0.0025–2 μg $kg^{-1}min^{-1}$. It is rapidly inactivated by plasma and tissue esterases [492]. The terminal elimination half-life is 10–20 min.

Remifentanil has a μ-opioid type side effect profile with strong CNS and respiratory depressant properties and a morphine-like addiction and dependence potential.

Trade name: Ultiva (Germany, UK, USA).

Sufentanil [*56030-54-7*], *N*-[4-(methoxymethyl)-1-[2-(2-thienyl)ethyl]-4-piperidinyl]-*N*-phenylpropanamide, *N*-[4-methoxymethyl-1-(2-thiophen-2-yl-ethyl)piperidin-4-yl]-*N*-phenylpropionamide, $C_{22}H_{30}N_2O_3S$, M_r 386.56, *mp* 96.6 °C; citrate (1 : 1) [*60561-17-3*], $C_{22}H_{30}N_2O_3S \cdot C_6H_8O_7$, M_r 578.68.

Synthesis: Sufentanil is obtained by condensation of *N*-(4-methoxymethylpiperidin-4-yl)-*N*-phenylpropionamide with 2-thiophen-2-yl-ethyl methanesulfonate [48, 493–496].

Opioid receptor binding: Sufentanil is a μ-selective opioid with an about 10-fold higher receptor affinity than fentanyl [497].

Sufentanil

Clinical use: Sufentanil [498] is a very potent and short-acting fentanyl derivative with preference for the μ-opioid receptor. It has strong sedating and analgesic properties and is used predominantly as an adjunct in anesthesia or as a primary anesthetic. Anesthetic doses induce respiratory depression and chest wall rigidity [499] which requires assisted ventilation. For pain treatment intravenous or epidural on-demand procedures are in use and a patch formulation for pain relief up to seven days is under development. Following parenteral administration sufentanil has a rapid onset and a short duration of action. The compound is very lipophilic and has a high plasma protein binding of ≈ 90 %. The short duration of action is more dependent on redistribution than on metabolic inactivation. Doses up to 8 μg/kg are adequate for pain treatment and higher doses up to 30 μg/kg for surgery [500]. Sufentanil has a morphine-type side effect profile and induces severe respiratory depression and chest wall rigidity in anesthetic dosages [501]. High dose levels have been associated with seizures. Prolonged use may induce tolerance and dependence.

Trade name: Sufenta (Belgium, Germany, France, Norway, USA).

3.1.1.4. Methadone and Congeners

Levomethadone [*125-58-6*], (*R*)-6-dimethylamino-4,4-diphenylheptan-3-one,

$C_{21}H_{27}NO$, M_r 309.45, *mp* 98–100 °C (*mp* racemic form [*57-42-1*] 78–79 °C), $[\alpha]_D^{20}$ −32° (*c* = 1.8, CH_3CH_2OH), hydrochloride [*5967-73-7*], $C_{21}H_{27}NO \cdot HCl$, M_r 345.91, *mp* 240–241 °C (*mp* racemic form [*1095-90-5*] 231 °C), $[\alpha]_D^{20}$ −169° (*c* = 2.0, water).

Synthesis [502–509]:

Levomethadone

Opioid receptor binding: Levomethadone is the μ-selective levorotatory enantiomer of racemic methadone [510]. It has an opioid receptor affinity in the range of morphine.

Clinical use: Levomethadone [511] is similar to morphine in potency and side effect profile. The compound has a high oral availability and a long duration of action [12, 513]. Methadone is extensively protein-bound and accumulation can occur during chronic administration. For pain treatment, the active dose range is 2.5–10 mg. Methadone can be given orally or by subcutaneous or intramuscular administration (2.5–10 mg in analgesia), but causes pain at the injection site.

The long duration of action makes the compound suitable for the substitution treatment of opioid addiction [514]. Whereas levomethadone is preferred for pain treatment, oral racemic methadone is widely used for the substitution treatment of opioid addiction [515].

Levomethadone has a morphine-like side effect profile with stronger respiratory depression and less sedation than morphine [516]. The compound has a morphine-type abuse and dependence potential. Because of its slow elimination withdrawal reactions are more protracted and less severe than with morphine [517].

Trade names: Eptadone (Italy), Dolophine (USA), Metasedin (Spain),Physeptone (UK), l-Polamidon (Germany).

Levomethadyl acetate [*34433-66-4*], l-α-acetylmethadol (LAAM), 4-dimethylamino-1-ethyl-2,2-diphenylpentyl acetate, [*S*-(*R**,*R**)]-β-[2-(dimethylamino)propyl]-α-ethyl-β-phenylbenzeneethanol acetate, $C_{23}H_{31}NO_2$, M_r 353.50; hydrochloride $C_{23}H_{31}NO_2 \cdot HCl$, M_r 389.96, *mp* 215 °C, $[\alpha]_D^{25}$ −60° (*c* = 0.2, water).

Synthesis: Levomethadyl acetate is prepared by reduction of dextromethadone and subsequent acylation [518].

Opioid receptor binding: Levomethadyl acetate has a moderate affinity for opioid receptor binding with selectivity for the μ-type. Higher binding affinity is induced by the active metabolites l-alpha-noracetylmethadol, normethadol and methadol [519].

Clinical use: Levomethadyl acetate is an orally active methadone derivative with a slow onset and a long duration of action. The compound is extensively metabolized and active metabolites contribute to the long duration of action. Levomethadyl acetate was used mainly for substitution treatment of opioid dependence [520]. Oral doses from 20 up to 140 mg are given every 2–3 d. Supplementation with short acting opioids is necessary during the first days because of the delayed onset of action.

Levomethadyl acetate induces opioid-type side effects with respiratory depression, bradycardia, and impairment of cardiac contractility [521]. The compound inhibits cardiac electric conductivity and increases the QT interval in the electrocardiogram [522] and may induce ventricular arrhythmias and Torsade de pointes [523]. Because of the cardiovascular side effects

(Q/T-interval prolongation), the compound was recently withdrawn from the market.

Trade name: Orlaam (USA).

Dextromoramide [*357-56-2*], (+)-(*S*)-3-methyl-4-morpholin-4-yl-2,2-diphenyl-1-pyrrolidin-1-yl-butan-1-one, $C_{25}H_{32}N_2O_2$, M_r 392.55, *mp* 183–184 °C, $[\alpha]_D^{25}$ +25.5° (*c* = 5, benzene), $[\alpha]_D^{25}$ +16° (*c* = 5, ethanol), D-tartrate [*2922-44-3*], $C_{25}H_{32}N_2O_2 \cdot C_4H_6O_6$, M_r 542.64, *mp* 189–192 °C, $[\alpha]_D^{25}$ +25.5° (*c* = 5, water), $[\alpha]_D^{25}$ +30.5° (*c* = 5, CH_3OH).

Synthesis [48, 524]:

Opioid receptor binding: Dextromoramide is a μ-selective opioid with a higher receptor affinity than morphine.

Clinical use: Dextromoramide tartrate [525] is a strong opioid, structurally related to methadone and is used in the treatment of severe pain. Dextromoramide has a high oral availability and is administered orally or rectally. The parenteral potency is in the range of morphine, but the duration of action is shorter. The compound has a morphine-type abuse and dependence potential.

Trade name: Palfium (France, UK, Netherlands).

Dextropropoxyphene [*469-62-5*], 1-benzyl-3-dimethylamino-2-methyl-1-phenylpropionate, [*S*-(*R**,*S**)]-α-[2-(dimethylamino)-1-methylethyl]-α-phenylbenzeneethanol propanoate (ester), $C_{22}H_{29}NO_2$, M_r 339.47, *mp* 75–76 °C, $[\alpha]_D^{25}$ +67.3° (*c* = 0.6, $CHCl_3$); hydrochloride [*1639-60-7*], $C_{22}H_{29}NO_2 \cdot HCl$, M_r 375.93, *mp* 163–168.5 °C, $[\alpha]_D^{25}$ +59.8° (*c* = 0.6, water).

Synthesis: 4-Dimethylamino-3-methyl-1,2-diphenyl-butan-2-ol is formed by Grignard reaction of 3-dimethylamino-2-methyl-1-phenylpropan-1-one with benzylmagnesium chloride. The preferred product is the α-diastereomer (75 % α-form = 1*SR*,2*RS* isomer, 15 % β-form). The α-form crystallizes and the diastereomeric β-form remains in solution, because of its better solubility. Racemic resolution to obtain the analgetically (+)-enantiomer can be performed on the pure α-Grignard product via fractional crystallization of the salts with D-camphorsulfonic acid. Alternatively the resolution can be achieved by treating the racemic Mannich product 3-dimethylamino-2-methyl-1-phenylpropan-1-one with (−)-dibenzoyltartaric acid in acetone as solvent [582, 585–587] .

Opioid receptor binding: Dextropropoxyphene has a μ-opioid receptor binding affinity lower than morphine. Binding at other opioid receptors is even weaker.

Clinical use: Dextropropoxyphene is a moderately potent opioid analgesic often combined with paracetamol or acetylsalicylic acid. As hydrochloride or napsylate it is used orally for the treatment of mild to moderate pain [529]. Adverse reactions in the therapeutic range are mild and include drowsiness, dizziness, sedation, and nausea. Overdosage can induce serious adverse events including profound sedation, respiratory depression, cardiovascular disturbances, convulsions, and psychotic reactions, often with fatal outcome [530]. Dextropropoxyphene has a relatively low abuse liability. Abuse by injection is impeded by severe irritations at the injection side.

Because of severe and often fatal intoxications the compound is more and more substituted by other weak opioids.

Trade names: Antalvic (France), Darvon (USA), Develin (Germany), Doloxene (UK).

Diphenoxylate [*915-30-0*], ethyl 1-(3-cyano-3,3-diphenylpropyl)-4-phenylpiperidine-4-carboxylate, $C_{30}H_{32}N_2O_2$, M_r 452.59; hydrochloride [*3810-80-8*], $C_{30}H_{32}N_2O_2 \cdot HCl$, M_r 489.06, *mp* 220.5–222.0 °C.

Synthesis: The reaction of ethyl 4-phenylpiperidine-4-carboxylate with 4-bromo-2,2-diphenylbutyronitrile yields diphenoxylate [48, 531].

Diphenoxylate

Alternatively, diphenylacetonitrile can be condensed with ethyl 1-(2-chloro-ethyl)-4-phenylpiperidine-4-carboxylate in the presence of sodium amide.

Opioid receptor binding: Diphenoxylate is the active metabolite of difenoxine [532] and has a high affinity and selectivity for the μ-type of opioid receptor.

Clinical use: Diphenoxylate [533] is a synthetic pethidine derivative with a limited access to the brain and marginal analgesic activity. After oral administration, it reduces intestinal motility and secretion and is used for the treatment of diarrhea. Side effects include dizziness, drowsiness, euphoria, anorexia, intestinal paralysis. Prolonged use of high dosages may induce morphine-like physical dependence. To avoid abuse, diphenoxylate is routinely combined with small amounts of atropine.

The compound is now substituted by loperamide, which has less CNS side effects.

Trade names: Reasec (Germany, Italy), Diaserd (France), Tropergen (UK), Lomotil (USA).

Loperamide [*53179-11-6*], 4-[4-(4-chlorophenyl)-4-hydroxypiperidin-1-yl]-*N*,*N*-dimethyl-2,2-diphenylbutyramide, 4-(4-chlorophenyl)-4-hydroxy-*N*,*N*-dimethyl-α, α-diphenyl-1-piperidinebutanamide, $C_{29}H_{33}ClN_2O_2$, M_r 477.04; monohydrochloride [*34552-83-5*], $C_{29}H_{33}ClN_2O_2 \cdot HCl$, M_r 513.51, *mp* 222–223 °C (decomp.).

Synthesis [48, 534, 535] (see next page).

Opioid receptor binding: Loperamide has a morphine-like affinity and selectivity for the μ-opioid receptor [536].

Clinical use: Loperamide [537] is a synthetic opioid subjected to extensive first-pass metabolization after oral administration. Therefore little intact drug reaches the systemic circulation and the central nervous system. Loperamide has no centrally mediated analgesic efficacy, but may have a clinically useful analgesic

effect via peripheral opioid receptors [539]. Systemic and central opioid side effects are widely missing. Orally administered loperamide acts locally in the gut by inhibition of intestinal motility and secretion [540]. Besides the strong μ-opioid action, calcium and calmoduline antagonism are involved in the antidiarrheal activity. The compound is used in doses of 4–8 mg for the treatment of acute and chronic diarrhea and for the management of colostomies and ileostomies [538]. Adverse effects include nausea, dry mouth, dizziness. High doses can induce toxic megacolon and paralytic ileus. The compound has no abuse and dependence potential and is meanwhile available as over the counter (OTC) product [542].

Loperamide

Trade names: Imodium (Germany, Belgium, USA, France), Arret (UK).

Loperamide is also marketed in many generic formulations.

Piritramide [*302-41-0*], 1′-(3-cyano-3,3-diphenylpropyl)-[1,4′]bipiperidinyl-4′-carboxamide, $C_{27}H_{34}N_4O$, M_r 430.59, *mp* 149–150 °C.

Synthesis: Piritramide is prepared by condensation of 4-piperidinopiperidine-4-carboxamide with 3,3-diphenyl-3-cyanopropylbromide [48, 543].

Piritramide

Opioid receptor binding: Piritramide is a μ-opioid with morphine-like affinity and receptor selectivity.

Clinical use: Piritramide [544] is a synthetic opioid analgesic used for the treatment of acute, preferentially postoperative pain. It is given in doses of 15 mg by the intramuscular, subcutaneous, or intravenous route. Piritramide has a morphine-like effect – side effect profile.

Trade names: Dipidolor (Germany, Belgium, Netherlands), Piridolan (Sweden).

3.1.2. Other Structures

Tilidine [*51931-66-9*], ethyl *trans*-2-dimethylamino-1-phenylcyclohex-3-ene-carboxylate, $C_{17}H_{23}NO_2$, M_r 273.17, *mp* 34 °C, *bp* (133.32 Pa) 95.5–96 °C; hydrochloride [*27107-79-5*], $C_{17}H_{23}NO_2 \cdot HCl$, M_r

309.84, *mp* 159 °C; hydrochloride hemihydrate $C_{17}H_{23}NO_2 \cdot HCl \cdot 1/2\ H_2O$, M_r 318.80, *mp* 125 °C.

Synthesis: Reaction of buta-1,3-dienyl-dimethylamine 4 with ethyl atropate 5 yields tilidine as a *cis*/*trans* mixture (*trans* : *cis* = 2 : 3). Most of the analgetically inactive *cis* isomer is separated as a zinc complex and the *trans* isomer is isolated as the hydrochloride. The cis isomer can be epimerized to the *trans* form by treating the epimeric mixture with acid [48, 545–548].

Opioid Receptor Binding: Tilidine itself has a low opioid receptor binding affinity, whereas the active metabolites nortilidine and bisnortilidine have a high affinity and selectivity for the μ-type of opioid receptor [549].

Clinical use: Tilidine [550] is rapidly metabolized to the active metabolites nortilidine and bisnortilidine. It can be given orally and parenterally and is used in single doses of 50–75 mg for the treatment of moderate to severe pain. Tilidine has a substantial abuse potential. To avoid parenteral misuse, oral preparations are combined in some countries with a small amount of naloxone hydrochloride. This is intended to induce withdrawal symptoms after illicit parenteral administration. After oral administration, the naloxone component is metabolically inactivated and does not inhibit analgesia. After parenteral administration the naloxone component is active and blocks the tilidine effect and can induce withdrawal reactions [551]. The combination with naloxone, in contrast to pure tildine, is available under normal prescription.

Trade names: Valoron (Germany, Switzerland), Tilidate (Spain).

Combination with naloxone: Tilidin-N, Valoron N.

Tramadol [*27203-92-5*], *cis*-2-dimethylaminomethyl-1-(3-methoxyphenyl)cyclohexanol, $C_{16}H_{25}NO_2$, M_r 263.38; hydrochloride [*36282-47-0*], $C_{16}H_{25}NO_2 \cdot HCl$, M_r 299.84, *mp* 180–181 °C.

Synthesis: Grignard reaction of 2-(dimethylaminomethyl)cyclohexanone (obtained by Mannich reaction of cyclohexanone, formaldehyde, and dimethylamine hydrochloride) and the Grignard reagent of 3-bromoanisole yields tramadol as a *cis*/*trans* mixture (*cis* : *trans* = 85 : 15). Tramadol (*cis* isomer) is separated from the reaction mixture by crystallization of the hydrochloride

salt. A crystallization process of the hydrate or hydrobromide salts is also described. The *trans* isomer can be epimerized to the *cis* isomer by strong acids [48, 552, 553].

Opioid receptor affinity: Tramadol [554] itself has a weak opioid receptor affinity, the active metabolite O-demethyltramadol shows μ-selective binding with an affinity about ten times lower than morphine.

Clinical use: Tramadol hydrochloride [555] is a centrally acting analgesic with a μ-opioid and nonopioid action component [556]. The nonopioid component acts spinally via inhibition of noradrenaline (NA) and serotonin (5HT) reuptake. Tramadol is a racemic mixture of two optical enantiomers and uptake inhibition and opioid properties are differentially distributed between the enantiomers [557]. Opioid receptor affinity is low, but like codeine, tramadol is biotransformed to the O-demethyl derivative (M1), which has an essentially higher μ-opioid receptor affinity and may be responsible for the opioid properties of the compound. Tramadol is marketed worldwide and has become one of the most important centrally acting analgesics [558]. It is used in single doses of 50–100 mg for the treatment of acute and chronic medium to severe pain. The compound has a high oral bioavailability and can be given by mouth, rectally, or by intramuscular, subcutaneous, or slow intravenous injection or infusion. Typical side effects are nausea, sweating, and dizziness. High doses may have a pro-convulsive effect. Tramadol shows a reduced level of opioid side effects like respiratory depression and constipation. It has a very limited abuse potential and in most countries is not subject to narcotic control.

Tramadol is used as a mono-compound or as a combination with paracetamol [559].

Trade names: Adolonta (Spain), Contramal (Belgium, France, Italy), Nobligan (Skandinavia), Tramal, Tramal Long (Germany, Switzerland, Austria), Tramacet (UK), Ultram (USA), Ultracet (USA), Xprim (France), Zydol (UK, Ireland).

Combination with paracetamol: Ultracet (USA), Zaldiar (Germany, Austria, Switzerland).

Tramadol is also marketed in many generic formulations.

3.1.2.1. Mixed Opioid Agonist – Antagonists and Partial Agonists

Mixed agonist – antagonists are opioid compounds that have in vivo relevant affinity for more than one type of opioid receptors, commonly for the μ- and κ-types. The compounds of this group are historically derived from the antagonist nalorphine. At the μ-receptor they act as antagonists or partial agonists with low intrinsic activity. At the κ-receptor they act mostly as agonists. These substances are used as analgesics and the κ-agonistic effect and/or the partial μ-agonistic effect is responsible for their analgesic efficacy. The side effect profile and the misuse potential depend on the relative prevalence of either component in the individual compound. The κ-component effects dysphoria, hallucinations, and other psychotic reactions, but induces a low level of respiratory depression and addiction. Compounds with a marked κ-agonistic component such as pentazocine are meanwhile withdrawn from the market because of their unpleasant side effect profile. The μ-component is responsible for respiratory depression, euphoria, and dependence potential. Compounds with a more μ-antagonistic profile have a low abuse potential and are not under narcotic drug control, compounds with a stronger μ-agonistic component are scheduled. Application of a mixed agonist-antagonist in an opioid pretreated patient may reduce analgesia and induce a withdrawal reaction.

Buprenorphine [*52485-79-7*], 17-cyclopropylmethyl-α-(1,1-dimethylethyl)-4,5α-epoxy-18,19-dihydro-3-hydroxy-6-methoxy-α-methyl-6,14-ethanomorphinan-7-methanol, $C_{29}H_{41}NO_4$, M_r 467.30, *mp* 209 °C; hydrochloride [*53152-21-9*], $C_{29}H_{41}NO_4 \cdot HCl$, M_r 504.10.

Synthesis [48, 424–427] (see next page).

Opioid receptor binding: Buprenorphine [560] has a mixed agonistic – antagonistic action profile with a high affinity at the μ-, κ-, and δ-opioid receptor. A ca. 100-fold lower affinity was observed at the ORL1-receptor. The compound shows a slow receptor dissociation which can explain some peculiarities in the pharmacological actions [561].

Clinical use: Buprenorphine [562] is used against moderate to severe pain, mostly for

chronic pain treatment. The potency is about 20–30 times higher than that of morphine. Buprenorphine may be used for anesthesia premedication or as adjunct to anesthetics. The compound has a long duration and a slow offset of action and is therefore suited for the substitution treatment of opioid addiction [563, 564]. Due to its partial agonistic properties buprenorphine can act in combination with full agonists as an antagonist, reducing their effect and precipitating a withdrawal reaction in opioid dependent persons. Antagonistic properties are seen in doses much higher than the analgesic dose range. Therefore no special precaution is necessary when changing the treatment with a standard opioid agonist to buprenorphine or vice versa [565]. Buprenorphine is given parenterally, orally (sublingual), or by the transcutaneous route as a patch. The doses for slow intravenous or intramuscular administration are 300–600 μg, the sublingual doses are 200–400 μg, both given every 6–8 h. Buprenorphine patches are available as a matrix patch formulations with release rates of 35, 52.5, and 70 μg/h.

The use of buprenorphine for opioid addiction becomes more and more important. For this indication, buprenorphine is used in doses up to 24 mg sublingually alone or in combination with naloxone.

Adverse reactions of buprenorphine are typical of μ-opioids and include respiratory depression, drowsiness, nausea, and vomiting. Respiratory depression often occurs delayed, is long lasting, and may need higher doses of naloxone [566, 567]. Buprenorphine has a limited abuse potential and withdrawal reactions, due to slow receptor dissociation, are mild and delayed.

Trade names: Buprenex (USA), Buprex, Subutex (Germany, France, USA), Temgesic (Germany, France, UK), Transtec (Germany, Austria, Switzerland.

Combination with naloxone: Suboxone (USA).

Butorphanol [*42408-82-2*], 11-cyclobutylmethyl-1,2,3,4,9,10-hexahydro-4α,10-propanophenanthrene-6,10α-diol, $C_{21}H_{29}NO_2$, M_r 327.22, *mp* 215-217 °C, $[\alpha]_D$ – 70° (c = 0.1, CH_3OH); tartrate [*58786-99-5*], $C_{21}H_{29}NO_2 \cdot C_4H_6O_6$, M_r 477.55, *mp* 217–219 °C, $[\alpha]_D$ – 64.0° (c = 0.4, CH_3OH).

Synthesis [48, 568–570] (see on top).

Opioid receptor binding: Butorphanol [571] is a mixed agonist – antagonist opioid with high μ- and κ-receptor affinity and full agonistic activity at the κ-receptor and partial agonistic – antagonistic effect at the μ-receptor.

Clinical use: Butorphanol [572, 573] is a fairly potent opioid analgesic. It is used for the treatment of moderate to severe pain, for migraine and headache [574] and as an adjunct to anesthesia. Butorphanol is orally inactive but can be given by the nasal route [574]. The usual administration is via the intramuscular or intravenous route. The intramuscular doses are 1–4 mg every 3–4 h, the intravenous doses are 0.5–2 mg. Nasal doses are ≈ 1 mg per spray in each nostril.

The plasma elimination half-life of butorphanol is in the range of 3 h. Butorphanol [571]

has a side effect profile combining morphine- and pentazocine-like symptoms. They include drowsiness, weakness, sweating, feelings of floating, and nausea. It has respiratory depressant properties similar to morphine but with a ceiling effect. As antidote naloxone can be used. Overt hallucinations or other psychotic effects are rare and less often reported than with pentazocine. The compound has a low abuse potential and has not been submitted to narcotic control.

Trade name: Stadol (USA).

Dezocine [*53648-55-8*], 15-amino-1-methyltricyclo[7.5.1.0^{127,255}]pentadeca-2,4,6-trien-4-ol, [5*R*-(5α,11α,13*S**)]-13-amino-5,6,8,9,10,11,12-octahydro-5-methyl-5,11-methanobenzocyclodecen-3-ol, $C_{16}H_{23}NO$, M_r 245.36; hydrobromide [*57236-36-9*], $C_{16}H_{23}NO \cdot HBr$, M_r 326.27, *mp* 269–270 °C.

Synthesis [48, 575, 576]:

Opioid receptor binding: Dezocine [577] is a mixed agonist – antagonist with binding affinity to the μ-opioid receptor in the range of morphine. The δ- and κ-affinity is 10–100-fold lower [578].

Clinical use: Dezocine [579, 580] is a medium-potent opioid and is suited for the treatment of moderate to severe pain. It is given by injection in the dose range of 5–20 mg. Side effects include nausea, vomiting, and drowsiness. Overdosing can be treated with naloxone. In opioid pretreated patients, dezocine may precipitate withdrawal symptoms.

Trade name: Dalgan (USA, no longer marketed).

Meptazinol [*54340-58-8*], 3-(3-ethyl-1-methylazepan-3-yl)phenol, 3-(3-ethyl-hexahydro-1-methyl-1*H*-azepin-3-yl)phenol, $C_{15}H_{23}NO$, M_r 233.35, *mp* 127.5–133 °C; hydrochloride [*59263-76-2*], $C_{15}H_{23}NO \cdot HCl$, M_r 269.81.

Synthesis [48, 581, 582]:

Opioid receptor binding: Meptazinol [583] is a partial μ-agonist with a high μ-receptor affinity. A selective action at a special subtype of μ-opioid receptor (μ-1 subtype, [584]) is controversial.

Clinical use: Meptazinol [585] is used parenterally (50–100 mg) or orally to treat moderate or moderately severe pain. The compound has a shorter duration of action than morphine. The most common side effects are nausea, vomiting, and dizziness. Sweating and hypotension can also occur. Meptazinol has opioid antagonistic properties and can induce withdrawal in opioid-dependent persons. The compound has a very low dependence potential and is not under narcotic drug control. The compound is reported to be relatively free of respiratory depressant activity, which was attributed to selective binding to a μ-1 subtype of the opioid receptor [584]. This is not confirmed by others and the effect may be alternatively explained by a cholinergic action component [583] of the compound. In accordance with a low κ-receptor affinity, the incidence of psychotomimetic actions and hallucinations is low.

Trade name: Meptid (Germany, UK).

Nalbuphine [*20594-83-6*], (5α6α)-17-(cyclobutylmethyl)-4,5-epoxymorphinan-3,6,14-triol, $C_{21}H_{27}NO_4$, M_r 357.44, *mp* 230.5 °C; hydrochloride [*23277-43-2*], $C_{21}H_{27}NO_4 \cdot HCl$, M_r 393.91, *mp* 291–292 °C (decomp.).

Synthesis: Starting material for the nalbuphine synthesis is oxycodone (see page 55). After ether cleavage to oxymorphone the product is acylated and the *N*-methyl group is removed by treatment with cyanogen bromide. The acetyl groups are hydrolyzed with dilute hydrochloric acid. The resulting 14-hydroxydihydronormorphinone 6 is N-alkylated with cyclobutylmethyl bromide, and the carbonyl group at C-6 is reduced [48, 586, 587].

Opioid receptor binding: Nalbuphine is a mixed agonist – antagonist opioid with a high affinity at the μ- and κ-opioid receptor. At the κ-receptor the compound is an agonist, at the μ-receptor a partial agonist with a very low intrinsic activity, thus acting more as a μ-antagonist [588].

Clinical use: Nalbuphine [589, 590] is an opioid analgesic with a mixed agonist – antagonist action profile. Analgesia is limited by a "ceiling" effect. The compound has a low oral availability and is used as hydrochloride only for parenteral application to treat moderate to severe pain and as adjunct to anesthesia. The dose for pain relief is 10–20 mg. The most frequent side effects are drowsiness, sweating, nausea, and vomiting. Hallucinations and psychotomimetic reactions are less frequent than with pentazocine, reflecting a relative weak κ-agonistic component of the compound. Nalbuphine induced respiratory depression is less severe than with morphine and is limited by a ceiling effect [591]. The dependence potential is low and nalbuphine is not subject to narcotic control.

Trade name: Nubain (Germany, France, UK, USA).

Nalorphine [*62-67-9*], (5α,6α)-7,8-didehydro-4,5-epoxy-17-(2-propenyl)morphinan-3,6-diol, $C_{19}H_{21}NO_3$, M_r 311.38, *mp* 208–209 °C, $[\alpha]_D^{25}$ −155.3° (c = 3, CH_3OH); hydrochloride [*57-29-4*], $C_{19}H_{21}NO_3 \cdot HCl$, M_r 347.84, *mp* 260–263 °C; hydrobromide [*1041-90-3*], $C_{19}H_{21}NO_3 \cdot HBr$, M_r 392.29, *mp* 258–259 °C (decomp.).

Synthesis: Diacetylmorphine (heroin) is demethylated with cyanogen bromide and hydrolyzed to normorphine, which is alkylated with allyl bromide to give nalorphine [48, 592].

Opioid receptor binding: Nalorphine [113] is a mixed agonist – antagonist with a high affinity and low intrinsic action at the μ- and κ-opioid receptors.

Clinical use: Despite a predominant antagonistic action profile nalorphine has substantial analgesic activity and was the first opioid combining analgesic activity with an antagonistic action. The compound is no longer used because of κ-agonistic type adverse reactions such as anxiety, hallucinations, and dysphoric mood alterations.

Pentazocine [*359-83-1*], 6,11-dimethyl-3-(3-methylbut-2-enyl)-1,2,3,4,5,6-hexahydro-2,6-methanobenzo[*d*]azocin-8-ol, (2α,6α,11*R**)-1,2,3,4,5,6-hexahydro-6,11-dimethyl-3-(3-methyl-2-butenyl)-2,6-methano-3-benzazocin-8-ol, $C_{19}H_{27}NO$, M_r 285.42, *mp* 145–148 °C; hydrochloride [*2276-52-0*], $C_{19}H_{27}NO \cdot HCl$, M_r 321.89; lactate (1 : 1) [*17146-95-1*], $C_{19}H_{27}NO \cdot C_3H_6O_3$, M_r 375.51.

Synthesis [48, 594, 595] (see right column).

Opioid receptor binding: Pentazocine [596] is a mixed opioid agonist – antagonist with agonistic effects at the κ- and partial antagonistic effects at the μ-type of opioid receptor.

Clinical use: Pentazocine is a potent analgesic with therapeutic dosages in the range of 25–100 mg. It is orally bioavailable and was used as hydrochloride or lactate in oral, parenteral, and rectal formulations for the treatment of moderate to severe pain. Pentazocine induces morphine-type side effects like dizziness, nausea, vomiting, sedation, and sweating. In addition, it can cause κ-agonist type psychotomimetic effects like hallucinations, nightmares and thought disturbances. Respiratory depression is weaker than with morphine and is subject to a "ceiling" effect.

The compound has a relevant abuse potential [597] and high doses may produce dependence of the morphine type. Pentazocine effects can be antagonized by naloxone.

Because of its side effect profile, the compound is no longer used.

3.1.2.2. Opioid Antagonists [598]

Opioid and narcotic antagonists (Table 2) are compounds with binding affinity at opioid receptors, but without intrinsic activity. They only block the receptor without inducing a genuine effect but are able to inhibit or reverse the actions of opioid agonists or partial agonists. Antagonists may or may not be selective for one opioid receptor type. Only antagonists with a high affinity and/or selectivity for the μ-receptor have clinical application. They are used to terminate medically desired effects of μ-opioid such as anesthesia, to reverse side effects like respiratory depression or to treat opioid intoxications. Acute administration of antagonists precipitates withdrawal reactions in opioid-dependent subjects. In the course of long-term treatment orally active antagonists are used for detoxification of opioid addicts.

Antagonists with δ- or κ-receptor selectivity have no clinical application but are widely used in opioid research.

Levallorphan [*152-02-3*], 17-(2-propenyl)-morphinan-3-ol, 1-*N*-allyl-3-hydroxymorphinane, $C_{19}H_{25}NO$, M_r 283.42, *mp* 180–182 °C, $[\alpha]_D^{25}$ −88.9° (CH_3OH); hydrogen tartrate (1 : 1) [*71-82-9*], $C_{19}H_{25}NO \cdot C_4H_6O_6$, M_r 433.50, *mp* 176–177 °C, $[\alpha]_D^{25}$ −39° (water).

Synthesis: Starting material for the levallorphan synthesis is 1-(4-methoxybenzyl)-1,2,3,4,5,6,7,8-octahydro isoquinoline (**1**) (preparation see page 54) [48, 599–602].

Opioid receptor binding: Levallorphan has a high binding affinity but a low intrinsic activity at the μ-opioid receptor.

Analgesic efficacy and clinical use: Levallorphan [603] is an opioid antagonist with practically no analgesic action. It has been used as one of the first relative pure antagonists for the treatment of opioid overdosage, to reverse opioid central depression and to antagonize opioid-induced respiratory impairment [604]. The compound is now replaced by naloxone [605].

Naloxone [*465-65-6*], (5α)-4,5-epoxy-3,14-dihydroxy-17-(2-propenyl)morphinan-6-one, $C_{19}H_{21}NO_4$, M_r 327.37, *mp* 184 °C (also reported as 177–178 °C), $[\alpha]_D^{20}$ −194.5° (*c* = 0.93, $CHCl_3$); hydrochloride [*357-08-4*], $C_{19}H_{21}NO_4 \cdot HCl$, M_r 363.84, *mp* 200–205 °C.

Synthesis: 14-Hydroxydihydronormorphinone 6 (see page 70) is N-alkylated with allyl bromide [48, 606, 607].

Opioid receptor binding: Naloxone [608] is a pure opioid antagonist with a high affinity and a limited selectivity for the μ-receptor.

Efficacy and clinical use: Naloxone [609, 610] has no analgesic activity. The compound is the standard antidote to treat opioid adverse reactions, opioid overdoses, or to stop an intended use of an opioid compound. Typical indications are inhibition of opioid-induced respiratory depression, termination of opioid anesthesia or protection of neonates following opioid treatment during labor. Naloxone has a short duration of action and repetitive administration may be necessary to antagonize longer acting agonists. To avoid parenteral misuse of non-scheduled oral opioid formulations (tilidine, pentazcocine), a small amount of naloxone is added which is orally inactivated, but is fully active after parenteral administration.

Naloxone is orally inactive and is only used parenterally in single or repetitive doses of 0.4–2 mg up to a total dose of 10 mg, as an intravenous bolus injection or by infusion. The compound is more potent against pure opioid agonists than against mixed agonist – antagonists. Caution should be used in opioid-dependent persons or in persons under high-dose opioid treatment, as naloxone may precipitate an acute withdrawal reaction. Naloxone is relatively free of side effects. Nausea, vomiting, and convulsions have occasionally been reported.

Trade names: Narcan (France, UK, USA), Narcanti (Germany, Austria).

Naltrexone [*16590-41-3*], (5α)-17-(cyclopropylmethyl)-4,5-epoxy-3,14-dihydroxy morphinan-6-one, $C_{20}H_{23}NO_4$, M_r 341.40, *mp* 168–170 °C; hydrochloride [*16676-29-2*], $C_{20}H_{23}NO_4 \cdot HCl$, M_r 377.87, *mp* 274–276 °C.

Synthesis:

a) Naltrexone is prepared in the same way as naloxone starting from oxycodone via the intermediate **6** except that the nitrogen atom is alkylated with cyclopropyl bromide [48, 611].

b)

Opioid receptor binding: Naltrexone has a high affinity and selectivity for the μ-opioid receptor [612].

Efficacy and clinical use: Naltrexone [613, 614] is a pure opioid antagonist and has no analgesic activity. Naltrexone has a higher intravenous potency and longer duration of action than naloxone. It has a higher oral bioavailability and is given by mouth to treat opioid dependence and to maintain abstinence during opioid detoxification [615]. In opioid-dependent persons, naltrexone induces an acute withdrawal reaction.

Trade names: Nalorex (France, UK), Nemexin (Germany), Revia (USA), Trexan (USA).

N-Methylnaltrexone bromide [*073232-52-7*], 17-(cyclopropylmethyl)-4,5a-epoxy-3,14-dihydroxy-17-methyl-6-oxomorphinanium bromide, $C_{21}H_{26}BrNO_4$, M_r 436.34, *mp* 251 °C, $[\alpha]D^{25}$ - ?° (c = 1.49, CH_3OH); N-methylnaltrexone iodide [*073232-53-8*], $C_{21}H_{26}INO_4$, M_r 483.34.

Synthesis: Methylnaltrexone is obtained by quaternization of *N*-(cyclopropylmethyl)-noroxymorphone (naltrexone) with methyl bromide in acetone/dimethylformamide [616]:

Efficacy and intended clinical use: *N*-Methylnaltrexone [617] is the polar derivative of naltrexone, which does not reach the central nervous system but can block intestinal opioid receptors. The compound is under development to counteract opioid induced bowel dysfunction such as constipation and megacolon [618].

Nalmefene [*055096-26-9*], *N*-(cyclopropylmethyl)-4,5α-6-methylenemorphinan-3,1β-diol, $C_{21}H_{25}NO_3$, M_r 339.43, *mp* 105–110 °C; hydrochloride [*58895-64-0*], $C_{21}H_{26}ClNO_3$, M_r 375.89, *mp* 188–190 °C.

Synthesis: Nalmefene is synthesized by a Wittig reaction of naltrexone with triphenylmethylphosphonium bromide in DMSO under basic catalysis of NaH.

Nalmefene

Nalmefene is a 6-methylene analogue of naltrexone. It is a pure opioid receptor antagonist and has a high affinity for the κ-opioid receptor. Nalmefene has a long duration of action and is used in oral and parenteral formulations.

Nalmefene is used to reverse opioid intoxication [619] and for the treatment of opioid dependence [620]. The compound is in clinical development for the treatment of alcoholism [621], to support smoking cessation and to control pathological gambling [622].

Trade name: Revex (USA).

3.2. Antineuropathic Analgesics and Other Non-opioid Compounds

3.2.1. Neuropathic Pain Treatment [623–629, 658, 659]

Definition: Neuropathic pain results from damage to the nervous system due to many diverse processes. The damage causes persistent, distressing pain, that is reputedly unresponsive to conventional analgesics. The International Association for the Study of Pain (IASP) defines neuropathic pain as pain initiated or caused by a primary lesion or dysfunction in the nervous system. This malfunction of the nervous system can occur at any point along the sensory pathway (peripheral nerve, dorsal root ganglion, and CNS). The term peripheral neuropathic pain is usually used to refer to abnormalities in the peripheral nervous system. Central pain is retained as the term when the lesion or dysfunction occurs in CNS.

Table 4. Etiological classification of neuropathic pain [623]

Injury	Examples
Infection/inflammation	
	• postherpetic neuralgia • HIV
Trauma	
	• post-amputation phantom limb pain • spinal cord injury • surgery
Ischemia	
	• diabetic neuropathy • central post-stroke pain
Compression	
	• sciatica • carpal tunnel • trigeminal neuralgia
Neoplasm	
	• invasion of neural structures • compression by tumor expansion
Iatrogenic	
	• vinca alkaloids • antiretrovirals • post-irradiation
Idiopathic	
	• multiple sclerosis • trigeminal neuralgia • complex regional pain syndrome

Classification: Neuropathic pain has been traditionally classified according to its etiology (Table 1) and tends to be chronic and unremitting. Patients with neuropathic pain are often difficult to treat, the pain is sometimes relatively unresponsive to conventional analgesics and thus a wide variety of drugs from many classes have been suggested for this indication. Table 4. indicates that neuropathic pain refers to a group of

painful disorders characterized by pain due to dysfunction or disease of the nervous system at a peripheral level, a central level, or both. In contrast to nociceptive pain, which results from the activation of pain receptors (nociceptors), neuropathic pain is the result of injury to the pain-conducting nervous system.

Symptoms: Neuropathic pain is a complex entity with many symptoms and signs that fluctuate, in number and intensity, with time. The descriptors associated with neuropathic pain have been described qualitatively as burning, stabbing, shooting, aching and electric shock-like, amongst others. Pain may be continuous or paroxysmal and felt superficially or deeply. It may also occur spontaneously, independent of a stimulus. Sensory changes in the injured area are common. There may be areas of sensory loss but also of altered sensation to cutaneous stimuli. Non-noxious stimuli, e.g. stroking, may elicit pain (allodynia). Mildly painful stimuli may cause excessive pain (hyperalgesia) and repetitive stimulation can cause an explosive build-up of pain that lasts well beyond the stimulus (hyperpathia). These sensory abnormalities can be classified by type of stimulus – thermal, mechanical, and chemical. Mechanically evoked events can be further subdivided into dynamic (brush-stroke evoked), static (pressure-evoked) and punctate.

Current Treatment Options in Neuropathic Pain. There are several rationales to guide treatment of patients with neuropathic pain. The most widely used at present is based on the etiology and anatomical distribution of the pain. Others have suggested a symptom-based approach on the premise that certain symptoms might respond best to specific classes of drugs. In clinical practise it is shown that one mechanism may lead to different symptoms and that a similar pain symptom or deficit may be produced by several different underlying mechanisms. At present, there is no single treatment that adequately and predictably controls neuropathic pain, nor does there seem to be any way of preventing the development of neuropathic pain following nerve injury. Management by a combination of both pharmacological and non-pharmacological approaches, ideally in a multidisciplinary pain clinic setting, seems to offer the best treatment options. Other interventions such as stimulation, blockade, or destruction of nerves and psychological treatments are also part of the armament for treating neuropathic pain. Table 5. gives an overview on the current available evidence-based treatment options for neuropathic pain.

Table 5. Evidence-based treatment options for neuropathic pain [623]

Drug class	Proposed mechanism of action	Examples
Tricyclic antidepressants	• unspecific sodium channel blockade • inhibition of norepinephrine and serotonin reuptake • blockade of α-adrenergic receptors	• amitryptiline • nortriptyline • desipramine • imipramine
Serotonin and/or norepinephrine reuptake inhibitors	blockade of serotonin and/or norepinephrine reuptake	• duloxetine • venlafaxine
Anticonvulsants	• unselective block of sodium channels	• benzodiazepines • carbamazepine • oxacarbazepine • phenytoin • lamotrigin • topiramate • zonisamide
Anticonvulsants	• selective block of calcium channels	• gabapentin • pregabalin
Local anesthetics (type 1b antiarrythmic drugs)	• unspecific sodium (and/or calcium) channel blockade	• lidocaine • mexiletine • bupivacaine
Drugs for the treatment of neurological disorders	• antagonism of the NMDA receptor	• memantine • dextromethorphan • ketamine
Opioids	• opioid agonism	• blockade of norepinephrine reuptake • increased serotonin release • morphine • tramadol • methadone

3.2.2. Individual Compounds

Baclofen [*1134-47-0*], β-(aminomethyl)-4-chlorobenzenepropanoic acid, δ-(aminomethyl)-*p*-chlorohydrocinnamic acid, γ-amino-β-(*p*-chlorophenyl)butyric acid, $C_{10}H_{12}ClNO_2$, M_r 213.66, *mp* 206-208 °C; hydrochloride, $C_{10}H_{13}Cl_2N$, M_r 250.12, *mp* 179-181°C.

Synthesis:

a.) Baclofen is synthesized by reaction of 4-chlorobenzaldehyde with ethyl acetonacetonate under catalysis of sodium ethoxide. The resulting condensation product is hydrolyzed to 3-(4-chlorophenyl)glutaric acid. Cyclization to 3-(4-chlorophenyl)glutaric anhydride and subsequent aminolysis yields 3-(4-chlorophenyl)glutarimide, which is finally transformed to baclofen [630, 631]

b.) Alternatively, baclofen can be obtained by reaction of ethyl-4-chlorocinnamate with nitromethane followed by hydrogenation and ester cleavage [630, 631].

Clinical use: Baclofen, a $GABA_B$ agonist, was initially launched in the 1970s for the oral or parenteral treatment of voluntary muscle spasticity due to cerebrovascular accidents, cerebral palsy, meningitis, multiple sclerosis (MS), spinal lesions, and head injury. Baclofen mediates its effect directly via the $GABA_B$ receptor. An analgesic action of baclofen administered systemically was first described more than 25 years ago and subsequently confirmed by many different groups. Despite the large volume of preclinical data that is now available, the use of baclofen as an analgesic in humans has been limited owing, in part, to rapid tolerance and adverse effects following systemic administration. Possibly, the only type of pain for which baclofen can be used systemically is trigeminal neuralgia. However, when administered intrathecally, baclofen is able to reduce central pain such as occurs in stroke [632].

Trade names: Gabalon, Lioresal (Germany, UK, Italy), Liorésal (France).

Carbamazepine [*298-46-4*], dibenzo[*b*,*f*]-azepine-5-carboxamide, $C_{15}H_{12}N_2O$, M_r 236.27, *mp* 204–206 °C (also reported as 190–193 °C).

Synthesis [633]:

Alternatively, 5*H*-dibenzo[*b*,*f*]azepine can be treated directly with potassium cyanate yielding carbamazepine [634].

Clinical use: Carbamazepine is an orally active anticonvulsant. It is used additionally in the treatment of manic depression and as an analgesic in trigeminal neuralgia and other neuropathic pain conditions [635]. Common side effects are dizziness, drowsiness, ataxia, visual disturbances, dry mouth, abdominal pain, nausea, and vomiting. Other adverse reactions include headache, arrhythmias, and heart block.

Trade names: Tegretal (Germany, Italy), Tegretol (UK, France, USA).

Clonidine [*4205-90-7*], (2,6-dichlorophenyl)-(4,5-dihydro-1*H*-imidazol-2-yl)amine, $C_9H_9Cl_2N_3$, M_r 230.09, *mp* 139 °C; monohydrochloride [*4205-91-8*], $C_9H_9Cl_2N_3 \cdot HCl$, M_r 266.55, *mp* 305 °C.

Synthesis [48, 636, 637]:

Clinical use: Clonidine is an α_2-adrenergic agonist and is primarily used in the cardiovascular field for blood pressure reduction (→ Antihypertensives, Section 5.1.2) [638]. The compound induces analgesia via central α_2-receptor interaction and can be used orally, parenterally or epidurally for pain treatment, often in combination with opioids or local anesthetics [639]. Epidural clonidine – opioid combinations are preferentially used for neuropathically maintained cancer pain. The compound is additionally used for migraine prophylaxis and to reduce opioid and alcohol withdrawal symptoms [640]. Clonidine frequently induces side effects like hypotension, sedation, drowsiness, dry mouth, and constipation. The compound is well absorbed orally.

Trade names: Duraclon (USA), Catapresan (Germany), Catapres (USA).

Duloxetine [*116539-59-4*], (+)-(*S*)-*N*-methyl-*N*-[3-(naphthalen-1-yloxy)-3-(2-thienyl)propyl]amine, (*S*)-*N*-methyl-γ-(1-naphthalenoxy)-2-thiophenepropanamine $C_{18}H_{19}NOS$, M_r 297.41, *mp* 118–122 °C, $[\alpha]_D^{20}$ +122 ° (*c* = 1.0, CH_3OH); hydrochloride [*136434-34-9*], $C_{18}H_{20}ClNOS_5$, M_r 333.88, *mp* 163–167 °C.

Synthesis: Reaction of 2-acetylthiophene with paraformaldehyde and dimethylamine in ethanol gives 3-(dimethylamino)-1-(2-thienyl)-1-propanone, which is enantioselectively reduced with a 2:1 complex of (2*R*,3*S*)-4-(dimethylamino)-3-methyl-1,2-diphenyl-2-butanol and $LiAlH_4$ in toluene to yield (*S*)-3-(dimethylamino)-1-(2-thienyl)-1-propanol. The condensation of (*S*)-3-(dimethylamino)-1-(2-thienyl)-1-propanol with 1-fluoronaphthalene catalyzed by NaH in DMSO affords the corresponding naphthyl ether (*S*)-*N*,*N*-dimethyl-3-(naphthalen-1-yloxy)-3-(thiophen-2-yl)propan-1-amine, which is finally monodemethylated with 2,2,2-trichloroethyl chloroformate and zinc in toluene and treated with oxalic acid [641, 642].

The ketone intermediate 3-(dimethylamino)-1-(2-thienyl)-1-propanone can also be re-

duced with $NaBH_4$ in ethanol to the racemic alcohol 3-(dimethylamino)-1-(thiophen-2-yl)-propan-1-ol, which is submitted to optical resolution with (*S*)-(+)-mandelic acid to provide the (*S*)-enantiomer [641, 642].

Reaction of thiophene-2-carboxylic acid with oxalyl chloride and triphenylphosphine gives the corresponding acyl chloride thiophene-2-carbonyl chloride, which is condensed with vinyltributylstannane, yielding 1-(2-thienyl)-2-propen-1-one. The addition of HCl to the double bond of 1-(2-thienyl)-2-propen-1-one affords 3-chloro-1-(2-thienyl)-1-propanone, which is reduced with BH_3 and the chiral (*R*)-oxazaborolidine catalyst in THF to give (*S*)-3-chloro-1-(2-thienyl)-1-propanol. Treatment of (*S*)-3-chloro-1-(2-thienyl)-1-propanol with NaI in acetone affords the (*S*)-3-iodopropanol derivative, which is condensed with methylamine in THF to provide (*S*)-3-(methylamino)-1-(2-thienyl)-1-propanol. Finally, this compound is condensed with 1-fluoronaphthalene by means of NaH in DMA [641, 642].

The Friedel – Crafts condensation of thiophene with 3-chloropropionyl chloride in presence of $SnCl_4$ in benzene gives the aforementioned 3-chloro-1-(2-thienyl)-1-propanone, which is reduced with $NaBH_4$ in ethanol to yield the racemic alcohol 3-chloro-1-(thiophen-2-yl)propan-1-ol. Optical resolution of 3-chloro-1-(thiophen-2-yl)propan-1-ol performed by means of immobilized CALB (Novozyme 435, Novo-Nordisk A/S) affords the enantiomer (*S*)-3-chloro-1-(thiophen-2-yl)propan-1-ol [643].

Clinical use: Duloxetine hydrochloride is an inhibitor of 5-HT reuptake and norepinephrine reuptake. The compound was launched in 2004 by originator Lilly for the treatment of major depression, urinary incontinence, and pain caused by diabetic peripheral neuropathy [643–645].

The drug is also undergoing phase III clinical trials at Lilly for the treatment of generalized anxiety and fibromyalgia.

Trade names: Cymbalta (Eli Lilly, UK, France, Italy, Germany), Yentrere (Eli Lilly, USA, UK, France, Italy, Germany), Arichaim (Boehringer Ingelheim, UK, France, Italy, Germany), Xeristar (Boehringer Ingelheim, UK, France, Italy, Germany).

Flupirtine [*56995-20-1*], ethyl[2-amino-6-(4-fluorobenzylamino)pyridin-3-yl]carbamate, $C_{15}H_{17}FN_4O_2$, M_r 304.32, *mp* 115–116 °C; monohydrochloride [*33400-45-2*], $C_{15}H_{17}FN_4O_2 \cdot HCl$, M_r 340.79, *mp* 214–215 °C; maleate (1 : 1) [*75507-68-5*], $C_{15}H_{17}FN_4O_2 \cdot C_4H_4O_4$, M_r 420.39, *mp* 175.5–176 °C.

Synthesis [48, 646–649]:

Clinical use: Flupirtine maleate [650] is an analgesic with an unknown mode of action. It is used in single doses of 100 mg orally and 150 mg rectally for the treatment of different pain conditions.

Trade name: Katadolon (Germany).

Gabapentin

Synthesis [651, 653–655]: In the original synthesis (Goedecke) cyclohexenone is reacted with ethyl cyanoacetate in the presence of ammonia to yield the Guareschi salt, which is hydrolyzed and decarboxylated to give 1,1-cyclohexanediacetic acid which is transformed by to the corresponding anhydride with acetic anhydride. This anhydride is treated with methanol to yield the half ester 2-[1-(methoxycarbonyl)cyclohexyl]acetic acid, which is subjected to a Curtius type rearrangement to give the isocyanate 2-[1-(isocyanatomethyl)cyclohexyl]acetic acid. The desired compound is obtained by hydrolysis of 2-[1-(isocyanatomethyl)cyclohexyl]acetic acid with HCl, followed by hydrochloric salt removal via anion exchange [651, 652].

The anhydride can also be treated alternatively with *N*-hydroxylamine to afford the *N*-hydroxyimide, which is converted to the *N*-benzenesulfonyloxylimide by reaction with benzenesulfonyl chloride. Subsequent reaction of the *N*-benzenesulfonyloxylimide with triethylamine in methanol gives the urethane ester methyl 1-(methoxycarbonyl)cyclohexanecarboxylate, which is submitted to HCl hydrolysis to afford the hydrochloride of gabapentin. The free amino acid is obtained from the hydrochloride via anion exchange.

The anhydride can also be treated with ammonia to yield cyclohexane-1,1-diacetic acid monoamide. In this route the compound is submitted to a Hoffman rearrangement to provide the target amino acid.

The reaction of 2-[1-(carbamoylmethyl)cyclohexyl]acetic acid with NaOCl and NaOH (a Hofmann rearrangement) gives the isocyanate intermediate, which without isolation hydrolyzes to the target gabapentin.

The condensation of cyclohexene-1-carbaldehyde with benzoylhydrazide in dichloromethane gives the corresponding hydrazone (*E*)-*N′*-(cyclohexenylmethylene)benzohydrazide, which is condensated under reductive conditions with trichloroacetyl chloride under catalysis of $BH_3/(CH_3)_2NH$ and Ms-OH (methanesulfonic acid) in diethyl ether to yield the adduct *N′*-(cyclohexenylmethyl)-*N′*-(2,2,2-trichloroacetyl)benzohydrazide. The cyclization of this adduct by means of CuCl and tetramethylenediamine (TMDA) in hot acetonitrile affords the spiro pyrrolidone, which is dechlorinated and debenzamidated by treatment with wet Raney nickel in ethanol at 110 °C to provide 2-azaspiro[4,5]decan-3-one. Finally, this compound is hydrolyzed with hot aqueous HCl to form the target gabapentin [653–655].

Clinical use: Gabapentin was developed as a structural GABA analogue but it has no direct GABAergic action and it does not affect GABA uptake or metabolism. Preliminary evidence points to the possible effect of gabapentin on the $\alpha 2\delta$ type of calcium channels.

The complex pharmacological mechanism by which gabapentin and the related compound pregabalin exert their clinical effect in epilepsy and neuropathic pain, remains unclear [656, 657].

Gabapentin has a clearly demonstrated efficacy in relieving pain and associated symp-

toms in patients with postdiabetic and postherpetic neuropathy. The starting dosage which can be used is 300 mg three times a day. Increase by 200 mg increments to 200–400 mg three to four times a day is recommended. As main side effects, sedation, dizziness, fatique, and pedal edema are reported [658, 659].

Trade name: Neurontin (Germany).

Gabapentin is also used in many generic formulations.

Lamotrigine [*084057-84-1*], 6-(2,3-dichlorophenyl)-1,2,4-triazine-3,5-diamine, 3,5-diamino-6-(2,3-dichlorophenyl)-1,2,4-triazine $C_9H_7Cl_2N_5$, M_r 256.09, *mp* 216-218 °C.

Synthesis: The reaction of the Grignard compound of 2,3-dichloroiodobenzene with CO_2 in diethyl ether gives 2,3-dichlorobenzoic acid, which is converted to the corresponding acyl chloride by refluxing with $SOCl_2$. The reaction of 2,3-dichlorobenzoyl chloride with cuprous cyanide and KI in refluxing xylene yields 2,3-dichlorobenzoyl cyanide. Finally, this compound is cyclized with aminoguanidine in DMSO to yield lamotrigine [660–663].

Condensation of 2,3-dichlorobenzoyl cyanide with aminoguanidine in the presence of polyphosphoric acid (PPA) as catalyst in hot acetonitrile yields 2,3-dichlorobenzoylcyanide amidinohydrazone, which is cyclized to the target 1,2,4-triazine by heating in refluxing propanol with or without DMSO.

Lamotrigine can also be obtained by the following route: Hydrogenation of 2,3-dichloronitrobenzene with H_2 over Raney nickel in methanol gives 2,3-dichloroaniline, which is diazotized with $NaNO_2$ and HCl and treated with CuCN to yield 2,3-dichlorobenzonitrile. Hydrolysis of the nitrile with NaOH in refluxing methanol/water affords 2,3-dichlorobenzoic acid, which is treated with hot $SOCl_2$ to provide the corresponding acyl chloride. Reaction of 2,3-dichlorobenzoyl chloride with CuCN and KI in refluxing chlorobenzene gives 2,3-dichlorobenzoyl cyanide, which is condensed with aminoguanidine by means of H_2SO_4/TsOH in hot toluene to yield 2,3-dichlorobenzoyl cyanide amidinohydrazone. Finally, this compound is cyclized by treatment with NaOMe in refluxing methanol to yield lamotrigine.

Clinical use: Lamotrigine is a phenyltriazine derivative and one of the newer antiepileptic agents, that stabilize neural membranes by blocking the activation of voltage-sensitive sodium channels and inhibiting the presynaptic release of glutamate. Lamotrigine was initially approved in the USA as add-on therapeutic for partial complex seizures. At doses of 50 to 400 mg/d lamotrigine has demonstrated efficacy in relieving pain in patients with trigeminal neuralgia refractory to other treatments, such as carbamazepine, phenytoin, or both. Pain reduction usually occurs at oral doses of more than 200 mg daily. However, lamotrigine must be dosed very slowly during the first six weeks of treatment to prevent a toxic rash. Recent negative results from a clinical trial indicated that more well-designed trials are needed to better define the role of lamotrigine as an analgesic drug. Main side effects are rash, dizziness, unsteadiness, and drowsiness [658, 659, 664].

Trade name: Lamictal (Germany, UK, France, Italy, USA).

Nefopam [*13669-70-0*], 5-methyl-1-phenyl-3,4,5,6-tetrahydro-1*H*-benzo[*f*][1,4]-oxazocine, $C_{17}H_{19}NO$, M_r 253.34; hydrochloride [*23327-57-3*], $C_{17}H_{19}NO \cdot HCl$, M_r 289.81, *mp* 238–242 °C.

Synthesis [48, 665, 666]:

Alternative route:

Clinical use: Nefopam [667] is a centrally acting analgesic without opioid properties. It induces inhibition of NA and 5-HT reuptake and has antimuscarinic and sympatomimetic actions which all might be relevant for its analgesic action. Nefopam is used orally and parenterally for the treatment of moderately severe pain. Side effects are nausea, vomiting, sweating, nervousness, tachycardia, and occasionally convulsions. Nefopam should not be used in combination with MAO inhibitors.

Trade names: Ajan (Germany), Acupan (Belgium, France, Italy, UK).

Phenytoin [*561-27-2*], diphenylhydantoin, 5,5-diphenyl-2,4-imidazolidinedione $C_{15}H_{12}N_2O_2$, M_r 252.27, *mp* 295-298 °C; monosodium salt [*690-93-3*], $C_{15}H_{11}N_2NaO_2$, M_r 274.26.

Synthesis:

a) Phenytoin is synthesized by cyclization of benzil with urea [668, 670].

Phenytoin

b) Alternatively phenytoin can also obtained by using benzophenone as a starting material [669, 670]:

Phenytoin

Phenytoin

Clinical use: Phenytoin became the first anticonvulsant to be used to treat neuropathic pain. The first clinical trials started in 1977. Current data indicate that the analgesic effect of phenytoin is achieved through the blockage of sodium channels, inhibition of presynaptic glutamate release and suppression of spontaneous neuronal ectopic discharges. Phenytoin is also used as a co-analgesic in combination therapy. As an oral starting dose, 200 mg at bedtime is recommended. An increase by 100 mg increments to 300–400 mg daily divided in 1–2 doses is possible. Main side effects are slurred speech, rash, unsteadiness, confusion, or blurry vision [658, 659].

Trade names: Epanutin, Phenhydan, Zentropil (Germany), Dihydan (France), Epanutin (UK), Dilantin (USA).

Topiramate [*097240-79-4*], 2,3;4,5-bis-*O*-(1-methylethylidene)-β-D-fructopyranose sulfamate, 2,3;:4,5-bis-*O*-(1-methylethylidene)-1-*O*-sulfamoyl-β-D-fructopyranose, $C_{12}H_{21}NO_8S$, M_r 339.36, *mp* 122-126 °C, $[\alpha]_D^{25}$ −34 ° (*c* = 0.4, CH_3OH).

Synthesis: Topiramate is synthesized by two methods [671, 672]: D-Fructose is reacted with acetone to produce the thermodynamically more stable bisacetonide. This bisacetonide is then condensed with sulfamoyl chloride in the presence of sodium hydride. Alternatively, the intermediate bisacetonide is reacted with sulfuryl chloride and pyridine in methylene chloride and then with sodium azide in acetonitrile to furnish the azido sulfate, which is reduced with copper powder in methanol [671, 672]

Topiramate

Alternatively the reaction of diacetone fructose with sulfamide in presence of of pyridine in xylene at 128-133 °C yields the target topiramate [673, 674].

Clinical use: Topimarate is a sulfamate-substituted derivative of D-fructose with the ability to block sodium channels, enhance GABA activity by interacting with a nonbenzodiazepine site of $GABA_A$ receptors, and selectively block AMPA/kainate glutamate receptors [658].

The empirical use of topimarate as an antinociceptive drug in humans was established before systematic, planned research on animal models of pain was initiated. Topiramate was initially launched in 1995 as monotherapy and adjunctive therapy for the treatment of epilepsy, specifically for the treatment of partial seizures, Lennox–Gastaut syndrome, and primary generalized tonic clonic seizures in patients inadequately controlled by other anticonvulsants. Topiramate is also used for the prophylaxis of migraine headaches.

The oral starting dose of topimarate is 25–50 mg at bedtime and can be increased by 25 mg increments weekly to 100–200 mg twice a day. Main reported side effects include confusion, weakness, weight loss, and kidney stones.

The compound had been under development for the treatment of neuropathic pain, bipolar disorders, obesity, pathological gambling, abuse and dependency, and for smoking cessation.

Trade names: Epitomax, Topamax, Topimax.

Ziconitide [*097240-79-4*], H-Cys-Lys-Gly-Lys-Gly-Ala-Lys-Cys-Ser-Arg-Leu-Met-Tyr-Asp-Cys-Cys-Thr-Gly-Ser-Cys-Arg-Ser-Gly-Lys-Cys-NH_2 cyclic S-3.1-S-3.16:S-3.8-S-3.20:S-3-15-S-3.25-tris(disulfide), omega-conotoxin MVIIA (reduced), cyclic (1-16),(8-20),(15-25)-tris(disulfide), $C_{102}H_{172}N_{36}O_{32}S_7$, M_r 2639.14.

Synthesis: Ziconitide is the synthetic form of the conotoxin ω-conopeptide MVIIA [675, 676] (see below).

Clinical use: Ziconotide is the synthetic equivalent of a naturally occurring conopeptide found in the marine snail *Conus magus*. Ziconotide is an N-type calcium channel blocker, that was launched in the USA by Elan in 2005 as a solution for intrathecal infusion for the management of severe, chronic pain in patients who are refractory to other treatments [675, 676]. Regulatory approval has been obtained for the product in the EU. The drug is administered through appropriate programmable microinfusion pumps, that can be implanted or external, and which release the drug into the fluid surrounding the spinal cord.

Ziconotide binds to N-type calcium channels located on the primary nociceptive (Aγ and C) afferent nerves in the superficial layers (rexed laminae I and II) of the dorsal horn in the spinal cord. Although the mechanism of action of the drug has not been established in humans, results in animals suggest that blocking of N-type calcium channels leads to a blockade of excitatory neurotransmitter release from the primary afferent nerve terminals which induces antinociception.

In July 2001, ziconotide received orphan drug designation from the EMEA for the treatment of chronic pain requiring intraspinal analgesia. The compound had also been under evaluation at Elan for the treatment of head injury.

Intended trade name: Prialt.

1. Introduction

General anesthetics are agents that temporarily produce a stupor- or sleeplike condition during which "painless" operation is possible. In this condition of general anesthesia (narcosis), consciousness, pain sensitivity, defense reflexes, and muscular reflexes are depressed to a large extent, whereas the vital centers of the medulla oblongata, particularly those controlling respiration and circulation, are relatively unaffected. In practice, the conditions depend entirely on the dosage of the anesthetic. Agents with too narrow a therapeutic range, i.e., too narrow a margin of safety between anesthetic dose and lethal dose, may not be employed.

The numerous theories regarding anesthesia either deal with the effectiveness or distribution of anesthetics within the body or speculate on their modes of action. Because inert gases, even the noble gases, are also effective anesthetics, the mode of action is believed to be a purely physical, reversible effect on the lipid-containing cellular membrane of the neurons. In principle, this affects all body cells. Only the higher sensitivity of the cells of the central nervous system (CNS) makes the desired gradual anesthetization possible with an appropriate dosage of the anesthetic agent.

Four different stages of anesthesia are distinguished:

1) The analgesic stage, permitting slightly painful procedures, such as changing dressings.
2) The excitation stage, which must be overcome quickly by premedication or additional anesthetic.
3) The tolerance stage, in which the centers of the cerebrum and spinal cord are inhibited, allowing surgical operations to be carried out.
4) The asphyxia stage, characterized by inhibition of the autonomic centers and the medulla oblongata (the vasomotor and respiratory centers), extreme muscle relaxation, and cessation of thoracic respiration. In practice, this stage must be counteracted immediately by appropriate measures, such as artificial respiration and/or infusion therapy; indeed, this stage should never be reached during anesthesia.

The tolerance stage can be subdivided into

a) Paralysis of the spinal cord and mesencephalon, slight relaxation of the muscles
b) Drop in blood pressure and body temperature, relaxation of the skeletal musculature
c) Relaxation of the abdominal musculature, onset of respiratory depression
d) Relaxation of the nonstriated musculature, lack of reflexes, difficult and deep breathing, abdominal breathing only, further drop

in blood pressure and body temperature, onset of hypoxemia, cyanosis

During emergence from the tolerance stage, the patient passes back through the excitation and analgesia stages.

Effective anesthesia is required to bring about

1) Unconsciousness
2) Complete analgesia and absence of pain reflexes
3) Relaxation of the muscles

The patient must receive sufficient anesthetic to fulfill the third requirement; in practice, this usually means overdosage regarding the first two requirements. Consequently, a combined technique is currently in use: other pharmaceutical agents, generally sedatives, neuroleptics, analgesics, and muscle relaxants, are used to support the anesthesia, particularly in the initial phase.

Depending on the duration of their action, anesthetic agents are termed long acting, short acting, or very short acting. Depending on how they are administered, they also can be divided into inhalation, intravenous, and combination anesthetics.

Inhalation (Pulmonary) Anesthetics. A large number of gases or vapors that are inhaled in a mixture with air or oxygen produce unconsciousness and analgesia. For practical purposes, however, only a few have proved efficacious.

Inhalation anesthetics are characterized by great stability. They are taken up quickly in the lungs and to a large extent are eliminated rapidly and mostly unchanged through the lungs (only minimally in the urine). They can be withdrawn immediately should an untoward incident occur; i.e., they can be controlled. Their main disadvantages are that they often cause a pronounced excitation stage and that many patients experience discomfort (postnarcotic nausea, vomiting). With inflammable gases the danger of explosion is always present.

Gas and vapor anesthetics exhibit different distributions between the lipophilic and hydrophilic phases and so have different solubilities in blood and different affinities to the lipid-rich nervous tissue of the CNS. The gases are less soluble in blood and require a higher partial pressure to maintain the tolerance stage. The steep concentration gradient makes it possible to induce and withdraw anesthesia quickly, thus providing better control of the narcosis.

The "minimum alveolar concentration" (MAC), a concept introduced in 1965, is a measure of the potency of inhalation anesthetics. It is expressed as the concentration in the alveolar air that prevents 50 % of patients from responding to pain stimuli. The MAC levels are changed by premedication agents or adjuncts, and anesthetic dosage always must be adjusted accordingly. However, the concentration of an anesthetic agent cannot be increased arbitrarily because of the narrow therapeutic range, which for most agents is ≈ 1.5.

Intravenous (Parapulmonary) Anesthetics. Metabolization and distribution gradually render intravenous agents ineffective; i.e., they are subject to processes over which the anesthesiologist has no influence. Further, these agents cannot be controlled once they have been administered. However, they are psychologically well tolerated by patients, and they are quite useful for brief narcosis and as induction agents for inhalation anesthesia, providing the basic anesthesia. Only intravenous anesthetics can be used when the airways must be maintained completely patent.

Combination Anesthesia. Inhalation or intravenous anesthetics, used singly, depend on dosage to achieve the conditions necessary for surgery: autonomic depression, sleep, analgesia, and muscle relaxation. Nowadays, preference is given to combinations of medications, which broaden the therapeutic range. Moreover, with several substances administered at minimal dosages the particular goals of anesthesia can be achieved.

Sleep-inducing anesthetics. To induce narcosis and regulate sleep, the short-acting barbiturates (the induction agents) – etomidate, steroid anesthetics, and some benzodiazepine derivatives – are used.

Neuroleptanalgesics. A stage that approximates that reached during the first stage of anesthesia can be attained by simultaneous administration of a potent analgesic and a neuroleptic agent. In this state of so-called neurolep-

tanalgesia, there are complete analgesia, psychic and motoric depression, and amnesia. The autonomic nervous system is depressed, whereas all important reflexes are retained. In general, the patient remains conscious, making this type of narcosis particularly suitable for operations in which active participation on the part of the patient is necessary, for example, brain, ear, and laryngeal operations. If higher doses of analgesics are given, artificial respiration is necessary. Commonly, the patient is premedicated with muscle relaxants, such as succinylcholine, with atropine, and even with anesthetics, such as propanidid or N_2O–O_2.

Neuroleptanalgesia is used for gentle narcosis, for lengthy operations, or for patients at risk in senium or with cardiovascular diseases.

Relaxants. Muscular relaxation is necessary for anesthesia and the operation. Some anesthetics produce muscle relaxation by affecting the central regulation of the tonus. However, peripheral muscle relaxation is achieved only by inhibiting the neurotransmitter acetylcholine with depolarizing substances or substances that block the acetylcholine receptor in the motor end plate. Such relaxants (→ Skeletal Muscle Relaxants) include tubocurarine, alcuronium, gallamine, pancuronium, decamethonium or suxamethonium, neostigmine, and pyridostigmine. Premedication with the anticholinergics atropine and scopolamine is common practice. Administered intramuscularly, these agents inhibit salivary and gastric secretions (prophylaxis against aspiration), prevent bradycardia, and provide protection against acute vagal reflexes.

2. Inhalation Anesthetics

2.1. Nitrous Oxide

Nitrous oxide [*10024-97-2*], nitrogen monoxide or laughing gas, N_2O, M_r 44.02, is a colorless gas with a slightly sweet odor and taste, *mp* –90.81 °C, *bp* −88.46 °C. At a pressure of 1 bar (100 kPa) one volume of water dissolves one volume of N_2O at 5 °C and 0.596 volumes at 25 °C. Nitrous oxide also is soluble in alcohol and ether. For manufacture → Nitric Acid, Nitrous Acid, and Nitrogen Oxides.

Nitrous oxide exerts a shallow anesthetic effect, MAC > 80. Although deep anesthesia cannot be achieved with it alone, it is used mixed with oxygen and ether or halothane as a basic anesthetic for all types of surgery because of its minimal toxicity. Further, N_2O does not irritate the airways. Nitrous oxide is always mixed with oxygen (20 %, in dentistry 20 – 50 %) to avoid anoxia. The use of nitrous oxide considerably reduces the requirements for other anesthetics and analgesics.

Trade Names. Stickoxydul (Hoechst) and others.

2.2. Hydrocarbons

Hydrocarbons have an anesthetic effect. However, despite their good anesthetic qualities and low toxicities, they are now rarely used because of the high risk of explosion. After serious explosions during anesthesia, ethylene and acetylene are no longer employed in Germany.

Cyclopropane [*75-19-4*], trimethylene, USP XIX, C_3H_6, M_r 42.08, is a colorless, odorless, inflammable gas, *mp* -127 °C, *bp* −33 °C. At room temperature it liquefies at 4 – 6 bar (400 – 600 kPa). The explosive range is between 2.4 and 10.3 vol % in air and between 12.5 and 60.0 vol % in oxygen. The blood – gas partition coefficient at 37 °C is 0.46. Cyclopropane is mixed with oxygen (15 – 30 % cyclopropane) for medical purposes. In contrast to nitrous oxide, cyclopropane (MAC 9.2) at concentrations of 20 % can produce anesthesia. It can be controlled readily and has a broad therapeutic range. Cyclopropane increases the sensitivity of the heart to catecholamines.

Cyclopropane is manufactured commercially from 1,3-dichloropropane with zinc in the presence of sodium iodide.

Trade Names. Cyclopropane (ICI; Mallinckrodt; Squibb). Cyclopropane USP is available in sealed orange metal cylinders or in chrome-plated cylinders with orange labels.

2.3. Halogenated Hydrocarbons

Low-boiling halogenated hydrocarbons exhibit anesthetic activity. Compared to hydrocarbons, they are more potent but also more toxic. Anesthetics previously in common use – chloroform,

carbon tetrachloride, and ethyl chloride – are now never or hardly ever employed because of their hepatotoxic and carcinogenic side effects. In addition, tribromoethyl alcohol is no longer employed in the major industrial nations. The chlorinated hydrocarbons increase the sensitivity of the heart to catecholamines.

Trichloroethylene [*79-01-6*], CCl_2=CHCl, M_r 131.4, is a colorless, noninflammable liquid with a characteristic chloroform-like odor, *bp* 87.2 °C. (For further information → Chlorinated Hydrocarbons.) Trichloroethylene is highly hepatotoxic and nephrotoxic and causes hepatocellular carcinomas in mice. In the presence of alkali, trichloroethylene decomposes to highly toxic dichloroacetylene and HCl. For anesthetic purposes, the substance is stabilized with thymol and mixed with a blue coloring agent.

Indication. For inhalation analgesia in obstetrics and for minor surgical procedures, but only with a special inhaler. Trichloroethylene (MAC 0.17) should not be used in a closed-circuit apparatus. Trichloroethylene is better tolerated than chloroform.

Trade Names. Anamenth (Brunnengräber) contains menthol as a stabilizer; Chlorylen (Schering); Ecrylène (Robert & Carrière, Paris); Narkosid (Heyl); Trethylene (Davies-Rose-Hoyt); Trichloran (Merck); Trilene (ICI; Ayerst).

Halothane [*151-67-7*], 2-bromo-2-chloro1,1,1-trifluoroethane, $CF_3CHBrCl$, M_r 197.39, is a colorless, noninflammable liquid with a characteristic sweet odor, *bp* 50.2 °C. Halothane is soluble in water to the extent of 0.345 wt %, miscible with ether, and sensitive to light. Anesthetic halothane contains 0.01 % thymol as a stabilizer.

Halothane is manufactured by chlorination of CF_3CH_2Br or bromination of CF_3CH_2Cl in the gas phase at 250 – 475 °C [2] or by the rearrangement [3]

$$CBrF_2CHClF \xrightarrow[50\,^\circ C]{AlCl_3} CF_3CHBrCl$$

Indication. Because of its potent and rapid effect, halothane (MAC 0.77) is used in special vaporizers mixed with oxygen and water. The high lipid – blood partition coefficient leads to considerable accumulation in tissue and fat. Halothane reduces the peripheral vascular resistance, increases the possibility of arrythmias, and has a negative effect on liver function. On repeated use it is hepatotoxic.

Trade Names. Fluothane (ICI Pharma); Halothan "Hoechst" (Hoechst); Halan (Arzneimittelwerk Dresden); Halovis (Vister, Italy); Narcotan (Spofa, Prague); Rhodialothan (Rhodia Pharma).

Teflurane [*124-72-1*], 2-bromo-1,1,1,2-tetrafluoroethane, CF_3CHFBr, M_r 180.95, a nonexplosive, noninflammable gas, *bp* 8 °C. Its anesthetic qualities are similar to those of halothane [4]. Teflurane is prepared by bromination of 1,1,1,2-tetrafluoroethane at temperatures above 400 °C [5].

Trade Name. Teflurane (Dow; Abbott)

2.4. Ethers

The ethers have a broad anesthetic range; i.e., the difference between the dose needed to produce the tolerance stage and the lethal dose is large. They have enjoyed a certain popularity as inhalation anesthetics. The best known, diethyl ether, usually is combined with other agents. There is always the danger of explosion in mixtures with oxygen or air. The solubility of ether in blood and tissue results in a 15-min induction period, which is accompanied by irritation of the mucous membranes and airways and by salivation. The recovery phase is long, and ether is no longer in routine use by anesthesiologists, despite its favorable effects on the bronchial musculature and cardiocirculatory system and its relatively good relaxant effect on the muscles.

Diethyl ether [*60-29-7*], H_5C_2-O-C_2H_5, M_r 74.12, is a mobile, colorless, inflammable liquid with characteristic odor, *bp* 34.6 °C. Mixtures of diethyl ether and air are explosive. Diethyl ether is miscible with short-chain alcohols, chloroform, and petroleum ether. An aqueous solution saturated with ether contains 8.43 wt % ether at 15 °C and 6.05 wt % at 25 °C. Ether saturated with water contains 1.2 wt % water at 20 °C (MAC 1.9). For details on preparation and purification → Ethers, Aliphatic.

Trade Names. Aether puriss, pro narcosi "Hoechst" (Hoechst); Aether puriss, pro narcosi "Bonz" (Bonz).

Divinyl ether [*109-93-3*], vinyl ether, CH_2=CH-O-CH=CH_2, M_r 70.09, is a mobile, colorless, inflammable liquid with a characteristic sweet odor, *bp* 28.4 °C. Approximately 4 % ethanol is added as a stabilizer. Divinyl ether may contain 0.0077 % of a stabilizer, phenyl-α-naphthylamine, that produces a slightly reddish fluorescence.

Divinyl ether is prepared by the reaction of liquefied alkali hydroxide or sodium alkoxide on β,β'-dihalodiethyl ether [6] or by pyrolysis of α,α'-dichlorodiethyl ether in the gas phase at 600 – 800 °C in the presence of barium chloride catalyst [7].

Indication. Divinyl ether is used for minor surgery, obstetrics, dentistry, and inducing anesthesia. A certain degree of hepatotoxicity rules out long-term use. Hypersecretion has also been observed. Divinyl ether increases and decreases in tissue levels faster than diethyl ether.

Trade Names. Vinydan (Lundbeck) contains *N*-phenylnaphthylamine as a stabilizer and absolute alcohol; Venesthene (May & Baker; Merck Sharp & Dohme); Vinether (Robert & Carrière, Paris); Ethydan (Lundbeck) is a 1 : 3 mixture of divinyl ether and diethyl ether.

2.5. Halogenated Ethers

The polyfluorinated ethers have analgesic and muscle-relaxing properties but are more difficult to control. In addition, some are readily inflammable. They fall between the ethers and the halogenated hydrocarbons in their effect on the heart. The importance of the fluorinated ethers varies from country to country. In 1985, enflurane was the most important. Some fluorinated ethers – such as sevoflurane, 1,1,1,3,3,3-hexafluoro-2-(fluoromethoxy)-propane [8] (Baxter); aliflurane, 2-chloro-1-methoxy-1,2,3,3-tetrafluorocyclopropane [9] (W. R. Grace); dioxychlorane, 4,5-dichloro-2,2-difluoro-1,3-dioxolane [10] (Ayerst); and thiomethoxyflurane, 2,2-dichloro-1,1-difluoro-1-methylmercaptoethane [11] (Ohio Medical Products) – are still being tested clinically.

Enflurane [*13838-16-9*], 2-chloro-1-(difluoromethoxy)-1,1,2-trifluoroethane, $CHClFCF_2$-O-CHF_2, M_r 184.5, *bp* 56.5 °C, is a colorless, noninflammable liquid with a pleasant odor. Enflurane (MAC 1.68) is used in special vaporizers and, depending on the stage of anesthesia, is mixed with various amounts of oxygen and nitrous oxide. Its advantage over halothane is the more rapid induction and withdrawal. Arrythmias are observed less frequently, which makes the combination with catecholamines less a problem.

Enflurane is prepared by dichlorination of the methyl group of 1-chloro-1,2,2-trifluoro-2-methoxyethane and replacement of these two chlorine atoms by fluorine [12], [13]:

$$CH_3-O-CF_2CHClF \xrightarrow[h\nu]{Cl_2} CHCl_2-O-CF_2CHClF$$
$$\xrightarrow[SbCl_5]{H_2F_2} CHF_2-O-CF_2CHClF + 2\,HCl$$

Trade Names. Ethrane (Deutsche Abbott); Ethrane (Ohio Medical Products).

Methoxyflurane [*76-38-0*], 2,2-dichloro-1,1- difluoro-1-methoxyethane, $CHCl_2CF_2$-O-CH_3, M_r 164.98, *bp* 104.65 °C, is a colorless liquid with a fruity odor. It is produced industrially by the addition of methanol to 1,1-dichloro-2,2-difluoroethylene in the presence of sodium methoxide [14].

Methoxyflurane is used with special vaporizers and, depending on the depth of anesthesia desired, is mixed with various amounts of oxygen and nitrous oxide. Its high lipid solubility gives it the lowest MAC, 0.2, found among inhalation anesthetics in use. It does not sensitize the heart to catecholamines; otherwise, the majority of its side effects are those of halothane (see page 4). Oxalate deposits and nephrotoxic fluoride concentrations are undesirable metabolic products of methoxyflurane.

Methoxyflurane may not be administered to patients with severe liver damage or renal insufficiency or those concomitantly receiving aminoglycoside antibiotics and tetracyclines.

Trade Names. Penthrane (Abbott) contains 0.01 % butylated hydroxytoluene as an antoxidant; Analgizer (Abbott); Methofane (Pitman-Moore).

Isoflurane [*26675-46-7*], 1-chloro-1-(difluoro- methoxy)−2,2,2-trifluoroethane, $CF_3CHCl\text{-}O\text{-}CHF_2$, M_r 184.5, is a colorless, noninflammable liquid with a faint odor, *bp* 48.5 °C. Isoflurane is prepared by chlorination of 2,2,2-trifluoroethoxydifluoromethane, itself obtained by alkylation of trifluoroethanol with difluorochloromethane [12], [15]:

$$CF_3CH_2OH + HCClF_2 \xrightarrow[80-95\,^\circ C]{KOH} CF_3CH_2-O-CHF_2 \xrightarrow{Cl_2} CF_3CHCl-O-CHF_2$$

Isoflurane (MAC 1.3) has a low blood – gas distribution coefficient, which leads to rapid recovery from the anesthesia. Myocardial functions remain intact, and as the depth of anesthesia increases, vasodilation progressively develops [16].
Trade Name. Forane (Ohio Medical Products).

Fluroxene [*406-90-6*], 2,2,2-trifluoro-1-vinyloxyethane, $CF_3CH_2\text{-}O\text{-}CH{=}CH_2$, M_r 126.8, *bp* 42.5 °C, is a colorless liquid with a pungent odor. It is inflammable and, at concentrations above 4 %, explosive in air. Fluroxene (MAC 3.4) generally is used in a mixture with oxygen and nitrous oxide. Several cases of liver damage have been observed.

The compound is prepared by catalytic vinylation of 2,2,2-trifluoroethanol in the presence of alkali-metal trifluoroethoxide [17]:

$$CF_3CH_2OH + CH{\equiv}CH \longrightarrow CF_3CH_2\text{-}O\text{-}CH{=}CH_2$$

Another synthesis is based on acetaldehyde-bis(trifluoroethylacetal), from which trifluoroethanol is split off in the presence of montmorillonite catalysts [18]:

$$(CF_3CH_2O)_2CHCH_3 \longrightarrow CF_3CH_2\text{-}O\text{-}CH{=}CH_2 + CF_3CH_2OH$$

Trade Name. Fluoromar (Ohio Medical Products).

3. Intravenous Anesthetics

Intravenous anesthetics, like inhalation anesthetics, can be used alone. Most have side effects. The majority cause respiratory depression. Administration of oxygen is recommended, particularly with barbiturates and thiobarbiturates. Intraarterial injection must be avoided because of the danger of tissue necrosis.

3.1. Barbituric Acids

The 5,5-disubstituted barbiturates have attained an extremely broad range of use as anesthetics and also are employed in other therapeutic areas (→ Hypnotics,→ Sedatives, and→ Antiepileptics).

Barbituric acid

The effective anesthetics are methylated at position 1, and usually one of the substituents at position 5 is unsaturated. The barbiturates are so-called haloencephalic anesthetics; i.e., the reversible inhibition of activity of all excitable tissue is particularly marked in the central nervous system. The redistribution of the lipophilic barbiturates from the well-perfused cerebral tissue into the peripheral storage depots of muscle and fatty tissue is more important for the cessation of anesthesia than is metabolism. Balanced distribution between plasma and fatty tissue is attained only after a relatively long period, e.g., for the thiobarbiturates, only after 1.5 – 2 h. Repeated administration of barbiturates carries with it the risk of accumulation.

Only a few of the many barbiturates have pharmacokinetic properties that make them suitable for use. The barbiturates are poor analgesics and muscle relaxants. The tolerance stage of anesthesia is reached quickly and can be maintained with an inhalation anesthetic. The barbiturates are employed generally for minor surgery and as induction agents for anesthesia. Phenobarbital is used only for premedication.

The following classification is based on a British evaluation of barbiturate and thiobarbiturate anesthetics [19]; in other countries, assessment is not necessarily identical:

Good, equally effective: thiopental, thiamylal, thiobutabarbital, thialbarbital

Insufficient, frequent side effects: hexobarbital, methitural, buthalital
Some advantages, some side effects: methohexital, narcobarbital

Methohexital sodium [*309-36-4*], sodium 5-allyl-1-methyl-5-(1-methyl-2-pentynyl)-barbiturate, M_r 284.30. The free acid [*18652-93-2*] forms colorless crystals, *mp* 60 – 64 °C. It is prepared by condensing diethyl allyl(1-methyl-2-pentynyl)malonate with *N*-methylurea [20].

Methohexital sodium is a short-acting anesthetic administered intravenously. It is very potent and has the shortest duration of action among the barbiturates used. A disturbing factor is that rather frequently it causes hiccups directly after injection. Patients are reported to recover rapidly from anesthesia. Abuse can lead to addiction.
Trade Names. Brevane (Elanco, USA); Brevital Sodium (Eli Lilly).

Hexobarbital [*56-29-1*], 5-(cyclohexen-1-yl)-1,5-dimethylbarbituric acid, M_r 236.26. The acid forms colorless crystals that turn pink on exposure to light, *mp* 146 °C. A 10 % aqueous solution of the sodium salt [*50-09-9*], M_r 258.25, has a pH of 11.5.

Hexobarbital sodium is prepared by condensation of methyl(cyclohexen-1-yl)cyanoacetic ester with dicyanodiamide to 5-(cyclohexen-1-yl)-5-methyl-2,6-diimino-3-cyanobarbituric acid, followed by methylation with dimethyl sulfate and hydrolysis with 25 % sulfuric acid [21].

Hexobarbital sodium is an intravenous anesthetic for short procedures and combination anesthesia. Hexobarbital is tolerated by tissue much better than thiopental and has proved efficacious for almost 50 years, at least for induction of anesthesia. Abuse can lead to addiction.
Trade Names (ampule with dry substance): Evipan-Natrium (Bayer); Evipal Sodium (Winthrop-Stearns); Cyclonal Sodium (May & Baker); Dorico Solubile (Winthrop); Hexanastab (Boots); Toleran inj. (Kwizda).

3.2. Thiobarbituric Acids

The anesthetic effect of the thiobarbituric acids differs from that of the barbiturates in that they produce a somewhat longer period of sleep after withdrawal of medication. Emergence is calmer and quicker. The duration of anesthesia can be lengthened considerably in patients having only limited fat deposits outside of the central nervous system (i.e., asthenic persons) or having fat deposits saturated by several injections of thiobarbiturates. The thiobarbiturates depress respiration more than the barbiturates and are less well tolerated by the veins.

The thiobarbituric acids are more acidic than the barbituric acids. They dissolve in aqueous alkali, but the heterocyclic ring opens after a time. They are prepared by condensation of substituted malonic esters, malononitrile, malononitrile esters, or malonamide esters with thioureas or *N*-alkylthioureas, whereby the imino derivatives initially produced are hydrolyzed to thiobarbituric acids [22].

Thiopental sodium [*71-73-8*], the sodium salt of 5-ethyl-5-(1-methylbutyl)thiobarbituric acid [*76-75-5*], M_r 264.35, a yellowish-white, crystalline, slightly bitter powder, is very soluble in water and soluble in alcohol. The compound is hygroscopic and has a weak unpleasant odor. The free acid forms colorless crystals, *mp* 158 – 159 °C. A 10 % solution of the sodium salt has a pH of 10.6.

It is prepared by condensation of thiourea with a disubstituted malonic ester [23].

Thiopental sodium is a short-acting intravenous anesthetic used for brief surgical procedures and induction of anesthesia. It is a potent,

rapidly effective hypnotic. Sleep ensues within 30 – 60 s. A disadvantage is the lengthy hangover. In the United States and Great Britain it is the most widely used injection anesthetic. Abuse can lead to addiction.

Thiopental sodium is used in a mixture with approximately 6 % sodium carbonate.

Trade Names. Farmotal (Farmitalia); Hypnostan (Leiras, Turku); Intraval (May & Baker); Leopental (Leo); Nesdomal (Specia); Pentothal (Abbott); Pentothal-Natrium (Deutsche Abbott); Thio-Barbityral (Amino, Neuenhof, Switzerland); Thionembutal (Abbott); Thiobarbital (Miro, Palma de Mallorca); Thiopental "Lentia" (Hormonchemie, Munich); Trapanal (Promonta; Byk Gulden).

Thiobutabarbital sodium [*947-08-0*], the sodium salt of 5-*sec*-butyl-5-ethylthiobarbituric acid, M_r 241.32, is a yellowish-white amorphous powder soluble in water and alcohol. The colorless crystals of the free acid [*2095-57-0*] melt at 163 – 165 °C. Thiobutabarbital is prepared from thiourea and a malonic ester [24].

It is a short-acting intravenous anesthetic. It is the least potent of the thiobarbiturates and therefore causes the least number of complications during anesthesia. The compound is available as 5 % and 10 % solutions.

Trade Names. Inaktin (Byk Gulden); Narkothion (Sanabo); Brevinarcon (Arzneimittelwerk Dresden).

Thiamylal [*77-27-0*], 5-allyl-5-(1-methylbutyl)-2-thiobarbituric acid, M_r 254.36, *mp* 132 – 133 °C. The sodium salt [*337-47-3*], M_r 276.36, is an amorphous powder soluble in water. It is prepared by condensation of thiourea with a malonic ester [25], [26].

The properties of this rapidly effective anesthetic are similar to those of thiopental.

Trade Names. Surital (Parke-Davis); Thiosecional (Eli Lilly); Bio-Tal (Philips Roxane, veterinary anesthetic).

Buthalital sodium [*510-90-7*], the sodium salt of 5-allyl-5-isobutyl-2-thiobarbituric acid, M_r 262.31, is a water-soluble amorphous powder. The free acid [*468-65-5*], M_r 240.33, melts at 147 °C. Buthalital sodium is prepared by condensation of thiourea with a malonic ester [27], [28].

Buthalital sodium is eliminated so rapidly that slow injection does not produce anesthesia [29]. For pharmacological properties, see [30].

Trade Names. Baytinal (Bayer); Transithal (May & Baker); Ulbreval (Wyeth).

Thialbarbital [*467-36-7*], 5-allyl-5-(cyclohexen-2-yl)-2-thiobarbituric acid, M_r 264.36, *mp* 79 – 81 °C. The sodium salt [*3546-29-0*], M_r 286.34, is a pale yellowish, water-soluble, amorphous powder.

Thialbarbital is prepared from thiourea and a malonic ester [31].

Trade Name. Kemithal (ICI; Avlon).

3.3. Miscellaneous Compounds

A miscellaneous group mainly includes compounds that are readily soluble in lipids and that must be brought into aqueous solution with solubilizers. They are generally short- and very short-acting anesthetics used for surgical intervention and induction of inhalation anesthesia.

Propanidid [*1421-14-3*], propyl 3-methoxy-4-(*N,N*-diethylcarbamoylmethoxy)-phenylacetate, M_r 337.42, is a colorless to pale yellowish water-insoluble oil. It is prepared from the propyl ester of sodium homovanillic acid and *N,N*-diethylchloroacetamide [32].

Propanidid

Propanidid is used as a very short- to short-acting intravenous anesthetic for minor surgery and gynecology. It is characterized by rapid onset of and quick recovery from anesthesia, producing surgical anesthesia for 3 – 4 min. Repeated injections can be used to prolong the anesthesia. Postanesthetic sleep does not occur because the propyl ester is hydrolyzed rapidly in the patient to form inactive 3-methoxy-4-(*N,N*-diethylcarbamoylmethoxy)phenylacetic acid. After 20 – 30 min the patients generally are completely responsive [33].

The commercial 5 % aqueous solution contains 20 % of the solubilizer Cremophor EL (polyethoxylated castor oil) [34]. Histamine release is sometimes observed, in part because of the Cremophor EL.

Trade Names. Epontol (Bayer; Theraplix); Propanidid (Riker); Fabontal (Bayer); Propantan (Leiras, Turku); Sombevrin (Gedeon Richter).

Ketamine [*6740-88-1*], 2-(*o*-chlorophenyl)-2-methylaminocyclohexan-1-one, M_r 237.74. The hydrochloride [*1867-66-9*] forms colorless crystals, *mp* 262 – 263 °C. Its solubility in water at 20 °C is 20 g per 100 mL.

It is prepared by bromination of *o*-chlorophenyl cyclopentyl ketone, which is then reacted with methylamine to give the methylimino alcohol. Thermolysis of the imino hydrochloride yields ketamine by ring expansion [35]:

Ketamine

Ketamine is a short-acting anesthetic effective for 5 – 30 min, depending on the amount injected. It is suitable for diagnostic purposes and for surgical procedures that do not require muscle relaxation. The occasional hallucinations that occur during anesthesia suggest a chemical relationship to phencyclidine, which was used as a short-acting anesthetic until identified as a dangerous drug of abuse.

The mode of action of ketamine differs from that of the barbiturates. It suppresses the activities of the cerebral cortex (consciousness) and the thalamic pain pathways (analgesia). Parts of the upper brainstem and the limbic system are not affected (so-called dissociative analgesia). The patient exhibits a characteristic superficial sleep with complete elimination of pain. Because of the psychomotor side effects, combination with neuroleptics and tranquilizers is necessary. Ketamine is used especially in pediatrics. The usual preparations are 0.1 % and 0.5 % solutions.

Trade Names. Ketanest (Parke-Davis); Ketaject (Bristol); Ketalar (Parke-Davis; Sankyo); Ketaset (Bristol); Vetalar (Parke-Davis, veterinary anesthetic).

4. Combination Anesthetics

Combination anesthetics are used only in combinations to produce balanced anesthesia (see page 2). Chemically and pharmacologically they belong to many different groups.

4.1. Sleep-Inducing Anesthetics

Etomidate [*33125-97-2*], ethyl (*R*)-(+)-1(α-methylbenzyl)-imidazole-5-carboxylate, M_r 224.28, is a white to yellowish crystalline or amorphous powder, *mp* ca. 65 – 70 °C. It is insoluble in water at pH 7, but soluble in acidic aqueous solutions at pH < 3. Etomidate is soluble in propylene glycol and readily soluble in alcohol.

The preparation of etomidate involves a modification of Jones' synthesis: α-phenylethylamine is alkylated with ethyl chloroacetate to the *N*-(α-phenylethyl)-glycine ester, whose NH group is formylated. This product is condensed with methyl formate and cyclized

with HCl-KSCN to yield ethyl 2-mercapto-1-(α-methylbenzyl)-5-imidazolecarboxylate, which is then oxidatively desulfurized [36]. The (*R*) isomer is obtained by separating the racemic acid with (*R*)-(+)-1-phenylethylamine.

Etomidate

Etomidate is administered intravenously as a short-acting anesthetic for the induction of lengthy anesthesia, especially for the induction of neuroleptanalgesia (Section 4.4) and inhalation anesthesia [37], [38]. Etomidate produces 3 – 5 min of sleep.

Trade Names. Hypnomidate (Janssen; Johnson & Johnson; Sanwakagaku Kankyusho; Abbott) as a 0.2 % solution; Radenarcon (Arzneimittelwerk Dresden).

Sodium oxybate [*502-85-2*], sodium γ-hydroxybutyrate, $HOCH_2CH_2CH_2COONa$, M_r 126.09, is recrystallized from alcohol and is soluble in water. It is prepared by saponification of γ-butyrolactone [39].

The substance is related to γ-aminobutyric acid, a cerebral metabolite that is supposed to be sleep inducing. When given i.p., it produces a shallow anesthesia (tolerance stage a: paralysis of the spinal cord and mesencephalon, slight relaxation of the muscles, see Chap. 1) that resembles natural sleep as seen via the electroencephalograph. It is employed as an anesthetic during labor and in combination anesthesia with nitrous oxide, barbiturates, or neuroleptanalgesics.

The sodium salt is available as a 24 % aqueous solution.

Trade Names. Somsanit (Kühler Chemie); Gamma-OH (Ebifarm); Anetamin (Sankyo); Gioron (Kaken-Ono, Japan).

Disoprofol [*2078-54-8*], 2,6-diisopropylphenol, *bp* 136 °C at 40 mbar, *mp* 19 °C, belongs to a new group of anesthetics. Its effects are similar to those of Althesin (see page 11) and thiopental (see page 7). However, it is more effective and may be given repeatedly without lengthening the reapplication interval. It has been in phase II of clinical trials since 1982 [40].

4.2. Benzodiazepines

Among the benzodiazepines, diazepam and flunitrazepam were used because of their sedative, anxiolytic, muscle relaxant, and anesthetic potentiating effects; initially, they were administered perorally but later also by injection. The frequency of pain at the injection site and of postoperative phlebothromboses led to the development of the water-soluble midazolam.

Midazolam maleate [*59467-70-8*], 8-chloro-6-(2-fluorophenyl)–1-methyl-4*H*-imidazo[1,5-a]-[1,4]benzodiazepine maleate [*59467-94-6*], M_r 441.59, *mp* 148 – 151 °C, is a stable, water-soluble powder. The solubility in water depends on pH: ≈ 85 mg/mL at pH 2.7 and 0.3 mg/mL at pH 7.6. The free base, M_r 325.78, melts at 152 – 154 °C. The maleate is subject to reversible ring opening. Below pH 4 the ring is open; above pH 4 the cyclic form is present. The anesthetic formulation is a buffered aqueous solution containing 2.5 mg/mL at pH 3.5.

The preparation starts with 7-chloro-5-(2-fluorophenyl)−1,3-dihydro-2*H*-1,4-benzodiaze-pinone [41]. For the literature, also see [42].

Midazolam is approximately twice as active as diazepam, causes less pain at the injection site, and has a shorter half-life than diazepam. Side effects: dose-dependent cerebral depression with tranquilization, sedation, and dryness. Reduction in blood pressure, respiratory depression, and cardiovascular effects were slight.

Trade Names. Dormicum (Hoffmann-La Roche, Switzerland); Hypnovel (Hoffmann-La Roche, United Kingdom).

4.3. Steroid Derivatives

A number of pregnane derivatives with oxygen substituents on C-3, C-20, and C-21 exhibit anesthetic properties without hormonal activity [43]. The preparations are used for brief narcosis and for induction of lengthy anesthesia. The first commercially available as an anesthetic was 21-hydroxypregnane-3,20-dione, as the water-soluble sodium hemisuccinate, under the generic name *hydroxidione* and by the trade names Presuren (Schering) and Viadril (Boehringer Mannheim; Pfizer).

The compound has been withdrawn in Great Britain and other countries, for, even when strongly diluted, it irritates the venous wall, increasing the risk of thrombosis, and elicits a long recovery phase. It is characterized by a late onset of the anesthesia after a relatively long, excitation-free induction period of 5 min. The induction period depends on the hydrolysis of the hemisuccinate ester to the active steroid alcohol. *Viadril G,* in which the hemisuccinate is combined with glycine, is supposed to be better tolerated. Most of the disadvantages can be avoided by dissolving the active pregnane derivative in Cremophor EL (BASF) [45].

A marked oversensitivity of patients to Althesin [45] led to the development of the water-soluble steroid *minaxolone* [44] (Glaxo-Allenbury), which is still being tested clinically.

Minaxolone

Alphaxalone [*23930-19-0*], 3α-hydroxy-5αpregnane-11,20-dione, M_r 332.49, forms colorless prisms, *mp* 172 – 174 °C, $[\alpha]_D^{26}$ +113.4 (c = 1.2 mg/mL in $CHCl_3$). It is prepared by reduction of 3,11,20-trioxo-5-α-pregnane with trimethyl phosphite in the presence of an iridium catalyst. Only this reducing agent forms the axial alcohol (3α) [46], [47].

Alphaxalone

Alphaxalone is the more potent component of *Althesin*. Addition of alphadolone increases the total amount of active steroidal anesthetic in the Cremophor solution.

Alphadolone [*14107-37-0*], 3α,21-dihydroxy-5α-pregnane-11,20-dione-21-acetate, M_r 390.52, forms colorless crystals, *mp* 175 – 177 °C, $[\alpha]_D^{26}$ + 97 (c = 1.02 mg/mL in $CHCl_3$). To prepare alphadolone, alphaxalone is reacted with lead tetraacetate in the presence of a Lewis acid, such as BF_3 etherate [47].

Alphadolone

Althesin is an effective intravenous anesthetic for short surgical procedures or for induction of lengthy anesthesia [45]. Doses of 0.050 – 0.075 mL per kg of body weight produce anesthesia in adults for 5 – 20 min and analgesia to surgical stimuli for 2 – 5 min. Althesin causes cardiodepressive side effects. Although it is used in countries in which French pharmaceuticals dominate, it is hardly used in Germany.

Trade Names. Althesin and Saffan (Glaxo); Aurantex (Glaxo, Bad Oldestoe).

4.4. Neuroleptanalgesics

Even with adequate somnolence and analgesia, surgical stress factors can be suppressed only if the activity of the deeper cerebral regions is subdued also. This is accomplished with small doses of neuroleptics (→ Neuropharmacology) to induce the so-called neuroleptanalgesia (see page 2). A potent analgesic is used in conjunction with a neuroleptic, the dosage usually adjusted for each individual. The first neuroleptanalgesic was the "coctail lytique" of Laborit and Huguenard, a mixture of pethidine as the analgesic, chlorpromazine as the neuroleptic, and promethazine as an antihistamine with pronounced sedative effect. In the course of further development, two combinations of neuroleptic and very potent analgesic emerged:

1) Haloperidol and phenoperidine (≈ 70 times more active than pethidine)
2) Droperidol and fentanyl (≈ 100 times more active than morphine)

Only the second is still important. A newer development is alfentanyl, *N*-[1-[2-(4-ethyl-4,5-dihydro-5-oxo-1*H*-tetrazol-1-yl)-ethyl]-4-(methoxymethyl)-4-piperidinyl]-*N*-phenylpropanamide hydrochloride (Johnson & Johnson), which was developed from fentanyl and is an effective anesthetic analgesic in phase III of clinical trials [48].

Alfentanyl

Droperidol [*548-73-2*], 1-[3-(4-fluorobenzoyl)-propyl]-4-(2-oxo-1-benzimidazolinyl)-1,2,3,6-tetrahydropyridine, M_r 379.44. The monohydrate melts at 145 – 146.5 °C. It is prepared by alkylating (2-oxo-1-benzimidazolinyl)-1,2,3,6-tetrahydropyridine with 4-fluoro-γ-chlorobutyrophenone [49].

Droperidol

Droperidol is a very potent neuroleptic from the phenylbutyrophenone group. It is never used in outpatient practice. To induce narcosis, 15 – 25 mg is injected, followed by further doses as needed. Narcosis begins rapidly, and the duration of action is short. Extrapyramidal symptoms are absent to a large extent. For anesthesia, the analgesic fentanyl is administered simultaneously.

Trade Names. Dehydrobenzperidol (Janssen, Düsseldorf); Thalamonal, Innovar in the USA, (Janssen) is a combination of droperidol with fentanyl. (One milliliter contains 0.05 mg of fentanyl base and 2.5 mg dehydrobenzperidol.)

Fentanyl [*437-38-7*], *N*-phenyl-*N*-[1-(2-phenylethyl)-4-piperidinyl]-propanamide, M_r 336.46, forms colorless crystals, *mp* 83 – 84 °C. The bitter-tasting dihydrogen citrate [*990-73-8*],

mp 149 – 151 °C, is soluble in water (1 g per 40 mL at 20 °C) and methanol. For preparation → Analgesics and Antipyretics.

Fentanyl belongs to the group of base-substituted propionanilide analgesics [50] and is a typical morphine agonist. Because of the danger of addiction, the short-acting fentanyl is used exclusively for anesthesia. A dose of just 0.2 – 0.3 mg produces complete short-term analgesia in adults. Because it depresses respiration, it is necessary to control breathing during neuroleptanalgesia. Afterward, respiratory depression can be alleviated by a morphine antagonist such as 1-*N*-allyl-3-hydroxymorphinan (Lorfan).

Trade Names. Fentanyl (Janssen, Düsseldorf), Sublimaze (Janssen); Thalamonal, see trade names for Droperidol.

1. Introduction

Aniline is the parent molecule of the family of aromatic amines (→ Amines, Aromatic). First isolated in the early 19th century (O. UNVERDORBEN 1826, F. RUNGE 1834, C. J. FRITZSCHE and N. N. ZININ 1841), the structure of the substance was finally proven in 1843 by A. W. VON HOFMANN, who was able to obtain aniline by the reduction of nitrobenzene.

The first technically applicable process (Bechamp process, see Chap. 3.2.2) for the production of aniline was developed as early as 1854.

Over the last 145 years aniline has become one of the hundred most important building blocks in chemistry. Aniline is used as an intermediate in many different fields of application as, for example, isocyanates, rubber processing chemicals, dyes and pigments, agricultural chemicals and pharmaceuticals.

2. Physical and Chemical Properties

Physical Properties. Aniline [*62-53-3*], $C_6H_5NH_2$, aminobenzene, benzamine (CAS name), phenylamine, aminophen when freshly distilled, is a colorless oily liquid with a characteristic sweet aminelike odor. Aniline turns to brown on exposure to air and light. Aniline is partially soluble in water and miscible with most organic solvents (e.g. ethanol, acetone, and benzene). Important physical properties of aniline are as follows [1]:

Molecular mass (M_r)	93.13
Boiling point (101.3 kPa)	184.4 °C
(4.4 kPa)	92 °C
(1.2 kPa)	71 °C

Chemical Properties. The chemistry of aniline is determined by the primary amino group (Fig. 1) and by the activated benzene nucleus (Fig. 2) [2].

Figure 1. Reactions of the amino group

Figure 2. Reactions of the aromatic ring

The lone electron pair on the nitrogen of the amino group is partially delocalized to the aromatic ring system [3]. Therefore aniline is only a weak base ($pK_a = 4.60$) as compared with aliphatic amines such as cyclohexylamine ($pK_a = 10.64$). Nevertheless aniline forms stable, water-soluble salts with strong mineral acids (e.g., hydrochloric or sulfuric acid). The formation of aniline sulfate can be used to protect the amino group of aniline against oxidation during subsequent synthesis steps.

Various alkylating agents (like alcohols, alkylhalides, alkylsulfates, and olefins) alkylate the amino group to form *N*-alkyl and *N,N*-dialkylaniline in Lewis acid catalyzed reactions at elevated temperature and pressure. The reaction of aniline with chloroform in a caustic potash solution produces phenylisocyanide. *N,N*-Diphenylthiourea is the product of the reaction of aniline and carbon disulfide in an alkaline alcohol solution. A characteristic reaction of primary aromatic amines like aniline is the formation of diazonium salts with nitrous acid. Aniline undergoes condensation reactions with alkylaldehydes. The most important reaction is the formation of 4,4′-methylenedianiline (MDA) by condensation of aniline with formaldehyde in the presence of hydrochloric acid. Aniline reacts with organic acids and acid derivatives to

form amides. Aniline undergoes a variety of oxidation reactions, depending on the oxidizing agent and the conditions. Mononuclear products like *p*-benzoquinone (MnO_2, H_2SO_4), bimolecular compounds such as azobenzene (air) or polymeric substances like aniline black (Cu or V, $Na_2Cr_2O_7$ or $NaClO_3$) may be formed (see Fig. 2).

The aromatic ring of aniline is catalytically hydrogenated to give cyclohexylamine and/or dicyclohexylamine at elevated temperature and pressure, depending on conditions and type of catalyst. The presence of the amino group activates the ortho and para positions of the aromatic ring and, as a result, aniline reacts readily with electrophilic substances. For example, the bromation of aniline yields 1,3,5-tribromoaniline under mild conditions. The reaction with sulfuric acid at high temperature forms almost exclusively 4-aminobenzene sulfonic acid (4-sulfanilic acid). Nitration of aniline (after protecting the amino group against oxidation by the formation of acetanilide) forms the 4-nitro compound. Numerous N-heterocyclic compounds can be obtained from aniline. For example quinoline is produced in the Skraup synthesis by condensation of aniline with glycerol or acrylaldehyde (acrolein) in nitrobenzene.

3. Production

3.1. Raw Materials

Most commercially used synthesis of aniline start from benzene. There is some literature about direct amination of benzene, but the high temperature and pressure required and the need to use an extreme excess of ammonia never allowed the development of an economic process [4]. DuPont and Mitsui Toatsu examined the oxidative amination process of benzene forming water as a byproduct [5].

Up to now, all technically applied aniline syntheses use an indirect way to produce aniline from benzene. In all cases a kind of derivatization is included as an intermediate step. In this step one of the two direct precursors of aniline is formed: nitrobenzene or phenol.

Nitrobenzene (→ Nitro Compounds, Aromatic). Nitrobenzene is manufactured commercially by the direct nitration of benzene in liquid phase using a mixture of nitric and sulfuric acid (mixed acid, nitrating acid). There are basically two thermodynamic ways for the nitration of benzene:

isothermal reaction
adiabatic reaction

In the isothermal process the nitration of benzene takes part in a reaction cascade of reactors (stirred cylindrical reactor or tubular reactor) at a temperature of 50 to 100 °C and ambient pressure. The temperature is maintained by internal and/or external cooling with cooling water. An advantage of the isothermal process, caused by the low reaction temperature, is the very low formation rate of byproducts (nitrophenols, picric acid) [6]. The nitrating acid is a mixture of fuming sulfuric acid (oleum) and concentrated nitric acid. In the adiabatic process the nitration of benzene takes part in a cascade of stirred reactors or a jet impingement reactor [7] at a temperature of 90 to 190 °C and ambient pressure. As nitrating acid a large volume of 65 to 85 % sulfuric acid and concentrated nitric acid are used. An advantage of the adiabatic process is that the reaction heat of the nitration, heating up the reaction mixture, is used to reconcentrated the spent sulfuric acid. This is done by azeotropic distillation of water/benzene, by stripping water with an inert gas, or distillation of the spent acid under reduced pressure.

Phenol (→ Phenol). The cumene oxidation (Hock process) process is the most important commercial process to synthesize phenol.

Cumene is prepared by alkylation benzene with propene using a carrier catalyst containing absorbed phosphoric acid, at temperature of ca. 230 °C and at a pressure of 3500 kPa [8]. Another process is the toluene oxidation route via benzoic acid.

3.2. Processes

Nitrobenzene is used as raw material for aniline production by all world producers with the exception of *Mitsui Petrochemicals Ind.* (Japan) who additionally uses phenol as starting material and *Aristech Chemical Corp.* (United States), who only uses the phenol route [9].

3.2.1. Catalytic Hydrogenation of Nitrobenzene

The highly exothermic catalytic hydrogenation ($\Delta H = -544$ kJ/mol at 200 °C) of nitrobenzene is performed both in the vapor and in the liquid phase in commercially used processes (see Fig. 3).

The exchange and utilization of the heat of reaction is a crucial point for all processes using nitrobenzene as a raw material [10].

Figure 3. Simplified flow sheet of the reaction route nitrobenzene to aniline
a) Hydrogenation; b) Separation; c) Dewatering; d) Rectification

3.2.1.1. Catalytic Vapor-Phase Hydrogenation

Nitrobenzene is hydrogenated to aniline, usually in more than 99 % yield, using fixed-bed or fluidized-bed vapor-phase processes. The most effective catalysts for the gas-phase hydrogenation of nitrobenzene seem to be copper or palladium on activated carbon or an oxidic support, in combination with other metals (Pb, V, P, Cr) as modifiers or promoters in order to achieve high activity and selectivity.

In the *Lonza process*, which is operated by First Chemical Corp., a homogenized feed of hydrogen and nitrobenzene is passed over a fixed-bed catalyst of copper on pumice with an inlet temperature of about 200 °C (example: 215 °C). The homogenization is done by spraying the nitrobenzene with the help of the fresh hydrogen feed into the heated (example: 240 °C) circulating gas stream at a fixed position. The molar ratio of nitrobenzene feed to total hydrogen is about 1 : 100 at the reactor inlet. The reaction products leave the reactor with a temperature of more than 300 °C (example: 325 °C). The heat of hydrogenation is used for steam production and for heating up the recycle gas stream. The reactor outlet is cooled down further in a condenser; excess hydrogen, crude aniline and water are separated. Aniline is purified by distillation [11, 12, 14].

Bayer operates conventional fixed-bed reactors using a palladium catalyst on a alumina support, modified in its activity by the addition of vanadium and lead [13] and claims the adiabatic hydrogenation of nitrobenzene over a fixed-bed catalyst of 1.5 to 4 wt % palladium on coke with 0.1 to 2 wt % lead as a modifier to reduce aromatic ring hydrogenation. At a pressure of 100 – 700 kPa a mixture of vaporized nitrobenzene and hydrogen in a molar ratio of 1 : 120 to 1 : 200 is fed to the adiabatic reactor with an inlet temperature of 250 – 350 °C. The height of the catalysts' bed in the reactor is 0.1 to 1. 0 m The reaction products leave the reactor without cooling at a maximum temperature of 460 °C. After leaving the reactor, the heat of reaction is used for the production of high pressure steam. A production unit can be built of several serial and/or parallel adiabatic reactors. After cooling down to 140 to 180 °C, the outlet of the final reactor is fed to a separation unit, where after further cooling crude aniline, crude wastewater, and the recycled hydrogen are separated under pressure. The crude aniline is purified by distillation [15–18].

BASF operates a vapor-phase, fluidized-bed process [19]. Nitrobenzene is partially evaporated by atomizing it with the aid of a hot stream of gas consisting substantially of hydrogen. The stream of gas is circulated in the presence of a fluidized catalyst, the reaction products are condensed, and aniline is separated from the isolated crude reaction products. One type of preferred catalyst is copper (≈ 15 wt %) on a silica support promoted with chromium, zinc, and barium. The two phase mixture of nitrobenzene and hydrogen is injected through nozzles located at several heights in the fluidized bed and the hydrogenation is carried out at 250 – 300 °C and 400 – 1000 kPa in the presence of excess hydrogen. The hot product gas is cooled by passing it through a heat exchanger, and aniline is iso-

lated in a liquid – gas separator. The reaction heat is used for steam production. For catalyst regeneration, after flushing the whole system with nitrogen, the organic material deposited on the catalyst surface is burned off at 200 to 250 °C with air. After completion of the regeneration and subsequent replacement of the air in the system with nitrogen, the catalyst is activated again by reducing the copper oxide to copper with hydrogen at 200 to 300 °C [20], [21].

3.2.1.2. Catalytic Liquid-Phase Hydrogenation

The industrial aniline processes of *ICI* and *DuPont* involve hydrogenation in the liquid phase. Liquid-phase hydrogenation processes are operated at 90 – 200 °C and 100 – 600 kPa. The liquid phase reaction may be carried out in slurry or in fluidized-bed reactors. Conversion of nitrobenzene is normally complete after a single reactor pass with yields of 98 to 99 %.

In the 1960s, *ICI* developed a continuous, liquid phase hydrogenation process, that used aniline as the solvent in a proportion > 95 wt % of the liquid phase. By operating at or near the boiling point of the solvent (usually at pressures < 100 kPa), some or all of the heat of the reaction is dissipated by allowing the reaction mixture to evaporate. Water is removed with the effluent vapors and sufficient aniline is returned to the reaction vessel to maintain steady state conditions. One preferred catalyst is finely divided nickel on kieselguhr [22].

DuPont hydrogenates nitrobenzene in liquid phase using a platinum – palladium catalyst on a carbon support with iron as modifier. The modifier provides good catalyst life, high activity, and protection against hydrogenation of the aromatic ring. The continuous process uses a plug-flow reactor that achieves essentially quantitative yields, and the product exiting the reactor is virtually free of nitrobenzene [23], [24].

A comparison of the catalytic liquid-phase and vapor-phase hydrogenation of nitrobenzene shows virtually no differences in yield and product quality for both processes. The liquid-phase process has the advantage of a higher space-time yield and no need for a recycle gas loop (lower energy requirement), the vapor-phase process has the advantage of a very effective utilization of the heat of reaction (steam production), no need for a product-catalyst separation and longer catalyst live.

3.2.2. Reduction of Nitrobenzene with Iron and Iron Salts

A historical variation of the nitrobenzene route is the *Béchamp process*, which uses iron and iron(II) chloride for the reduction.

This process is more than one hundred years old, but still used in two *Bayer* aniline plants. Nowadays the product of interest is no longer the aniline, but the colored iron oxide pigments, that are formed as byproducts. In the Béchamp process nitrobenzene is reduced in an agitated reaction vessel with iron(II) chloride solution and ground iron fillings. The reactor is filled with the total amount of water required for the reaction (aniline water from aniline distillation), 20 % of the iron, the total amount of catalyst needed, and about 5 % to 10 % of the total nitrobenzene feed. Under intense agitation the reactor content is heated up to reflux. After the reduction has started the remaining nitrobenzene and iron are added slowly to avoid excessive temperature and pressure buildup. For the completion of the reduction the vessel is heated up to 100 °C for two more hours after the end of the iron/nitrobenzene addition. The reaction is completed in about 8 to 10 h [25].

The reaction mixture is neutralized with lime; it is then transferred to a separator, and the organic phase containing the aniline is withdrawn. Aniline is recovered from the organic phase by water stripping and distillation. Residual aniline is recovered from the material remaining in the separator before the iron oxide powder slurry is processed into a fine particle, colored pigment. The color of the iron oxide byproduct can be controlled by additives to the reaction medium, by the use of different types of iron, and by subsequent calcination conditions [26].

3.2.3. Amination of Phenol

In the commercial phenol route developed by *Halcon*, phenol is aminated in the vapor phase using ammonia in the presence of a silica – alumina catalyst.

$\Delta H = -544$ kJ/mol

The reaction is mildly exothermic ($\Delta H = -8.4$ kJ/mol) and reversible, so high conversion is obtained only by the use of excess ammonia (mole ratio of 20 : 1) and a low reaction temperature, which also reduces the dissociation of ammonia. Byproduct impurities include diphenylamine, triphenylamine and carbazole. Their formation is also inhibited by the use of excess ammonia. Yields based on phenol and ammonia are $\geqq 96$ % and 80 %, respectively [28].

In the process (Fig. 4) phenol and fresh and recycle ammonia are vaporized separately (to prevent yield losses) and combined in the fixed bed amination reactor (a) containing the silica – alumina catalyst. After the reaction at 370 °C and 1.7 MPa, the gas is cooled, partly condensed and the excess ammonia is recovered in a separation column (b), compressed and recycled. The condensation product is passed through a drying column to remove water and then through a finishing column to separate aniline from residual phenol and impurities in vacuum (less than 80 kPa). The phenol, containing some aniline (azeotropic mixture) is recycled [29], [30].

Figure 4. Simplified flow sheet of the reaction route phenol to aniline
a) Amination; b) Ammonia recovery; c) Dewatering; d) Rectification

Comparison of the phenol route to the nitrobenzene route, both starting from benzene, shows four steps for the former (cumene to phenol involves two steps via the intermediate cumene hydroperoxide) versus two for the latter. The nitrobenzene route has an overall advantage in yield and lower total energy requirements. The phenol route has an advantage in prolonged catalyst life and product quality. It is the preferred method if low cost phenol is available (phenol producers).

4. Quality Specifications

The common standard specification of commercial-grade aniline is listed below:

Aniline	min. 99.9 %
Nitrobenzene	max. 2 ppm
Water	max. 500 ppm
Color	max. 100 APHA

For special applications the concentration of trace impurities like cyclohexylamine, cyclohexanol, cyclohexanone, toluidines, phenol, phenylcyclohexylamines, and dicyclohexylamine may be specified as well.

The analysis of the specified organic impurities is normally carried out by gas chromatography using a nonpolar stationary phase (dimethylpolysiloxane) and a flame ionization detector.

The water concentration in aniline is determined with the coulometric Karl-Fischer titration.

The color of the aniline is determined spectrophotometrically. Freshly distilled aniline is a colorless liquid (< 10 APHA) which becomes brownish by exposure to light and air.

5. Handling, Storage and Transportation

Aniline is slightly corrosive to some types of metal. So all amphoteric materials such as aluminum, copper, tin, zinc, and alloys containing one of these metals (brass, bronze) are not suitable for the handling of aniline, as they are corroded by it. For normal applications carbon steel or cast iron are appropriate materials for the aniline handling or storage. Only if discoloration

must be kept to minimum, aniline should be stored and transported in stainless steel equipment with proper nitrogen blanketing. Suitable gasket materials include for example graphite, polytetrafluoroethylene or poly(vinylidene fluoride), best reinforced with glass fiber.

Aniline is transported in drums, containers for the transportation on rail, water and street, railway tank cars and tank trucks as well as in tanks of ships for river and sea transportation.

Aniline is classified as a hazardous chemical substance for transportation (UN no. 1547). Because of its chemical properties it is classified as a poisonous liquid (class 6.1 12 b) class b (dangerous substance). Therefore, aniline must be transported following the Hazardous Materials Transportation Act regulations regarding loading, handling, and labeling.

6. Uses

In 1996 aniline was known to be used in more than 300 different end products (see Table 1). Thereof the polyurethane building block 4,4-methylene-di-paraphenylene isocyanate (MDI), accounting for 2/3 of the total demand, was of paramount importance. With an expected growth well above the increase of the average global gross domestic product, MDI in future will extent its position as dominating outlet for aniline even further.

Table 1. Worldwide consumption of aniline by application

Application	Percentage of consumption
MDI	65 %
Rubber processing chemicals	18 %
Dyes and pigments	5 %
Agricultural chemicals	4 %
Pharmaceuticals	2 %
Cyclohexylamine/dicyclohexylamine	2 %
Miscellaneous	4 %

6.1. Methylene Diphenylene Isocyanate (MDI)

MDI is one of the principal isocyanates that is reacted with alcohols such as polyols and polyetherols to produce polyurethanes (PU).

MDI based PU systems are mainly used in construction, furniture, automotive industry, and insulation. Due to the wide spectrum of traditional end uses and new fields of application MDI-PU will continue to show a strong growth especially in emerging markets.

Worldwide production capacity for MDI in 1996 was 2.35×10^6 t. Biggest producer was Bayer (capacity: 580×10^3 t), followed by ICI, BASF, and, Dow. Whereas ICI and BASF are fully back-integrated (i.e., self-sufficient), Bayer and Dow to a certain extent depend on aniline supplies from third parties.

After double digit growth rates in the mid 1990s, future use of aniline for MDI is projected to grow at a more modest rate of 6 – 8 % per year.

A typical MDI process used by commercial producers is as follows:

A mixture of polymeric methylenephenylamines is prepared by condensing aniline with formaldehyde in the presence of HCl. The reaction involves intermediate formation of amine hydrochlorides, which subsequently are neutralized with caustic soda. The reaction usually is run with an excess of aniline at subatmospheric pressure and temperatures between 70 and 105 °C. The yield is about 96 %.

The polyamine product is converted to a crude mixture of isocyanates by reaction with phosgene in a solvent. Reaction temperature is about 120 °C, pressure is 345 kPa, and yield ca. 97 %. Chlorobenzene is removed by distillation. The crude is separated by vacuum distillation into pure MDI and polymeric MDI. Hydrogen chloride is produced as a byproduct of the reaction.

6.2. Rubber Processing Chemicals

In the first decade of this century pure aniline was used as a vulcanization accelerator. The call for higher effectiveness and safer handling led to the development of aniline based mercaptothiazole and sulfenic amide accelerators (→ Rubber, 4. Chemicals and Additives, Chap. 2.3.1.) which at present account for ca. 80 % of all vulcanization accelerators used worldwide.

Of even bigger importance for aniline within the rubber processing chemicals sector are antidegradants (i.e., antioxidants, antiozonants) such as paraphenylenediamines (PPD), quinolines, and diphenylamine (→ Rubber,

4. Chemicals and Additives, Chap. 3.2.1.). Aniline is feedstock to roughly 70 % of all antidegradants consumed worldwide.

Future use of aniline in the rubber industry is forecasted to increase by 2 – 3 % per year, equivalent to the worldwide growth in demand for synthetic and natural rubber.

6.3. Dyes and Pigments

Intermediates for dyes and pigments cover more than 50 % of all known formulations using aniline as a raw material, albeit most of them are of minor importance. The largest classes are the mono-, di-, and triazo compounds. Production of dyes and pigments has shifted toward Asian countries, such as China and India. However, some world-scale dyes and pigments plants in Europe and NAFTA (United States, Canada, Mexico) are still using aniline, e.g., for the production of indigo. Since the industrial realization of the chemical indigo syntheses at the end of the 19th century by BASF, indigo (→ Indigo and Indigo Colorants) is the most important dye based on aniline.

Worldwide growth for this application is expected to be at a low rate of 1 – 2 % per year.

6.4. Agricultural Chemicals

More than 40 active substances for pesticides (herbicides, fungicides, and insecticides) use aniline as raw material. Most important are amide and urea herbicides. NAFTA-located companies stand for more than 50 % of the world′s aniline consumption for agricultural chemicals. Aniline-based active substances are predominantly in the later stage of their life cycle and are about to be substituted. Global consumption therefore is forecasted to decrease by 1 – 2 % per year.

6.5. Pharmaceuticals

As a stable, although small outlet, aniline is mainly used for preparation of analgesics, antipyretics, antiallergics, and vitamins. A certain growth in demand for drugs is expected for the next five years, counterbalanced by a decreasing aniline consumption for production of vitamins where the aniline route is being abandoned in favor of fermentation technology.

6.6. Cyclohexylamine/Dicyclohexylamine

In the 1990s aniline became the raw material of choice for the production of these amines. Both are predominantly used as intermediates for sulfenamide vulcanization accelerators. Cyclohexylamine is also used in large quantities as corrosion inhibitor and feedstock for cyclamates.

Whereas the usage of these amines in accelerators and water treatment is expected to grow at a rate of ca. 3 – 4 % per year, the consumption of cyclohexylamine for production of cyclamates has fluctuated considerably and is difficult to predict. A boost in demand can be expected should the FDA lift the ban on the usage of cyclamates as artificial sweeteners in the United States.

6.7. Miscellaneous

Among various other applications (production of alkylanilines, optical brighteners, sulfonic acids, etc.) the consumption of aniline for synthesis of aramid fibers is worth mentioning. Aramids are suitable for a wide spectrum of applications, mainly as substitutes for steel, showing equivalent reinforcement characteristics at far lower weight. Because of additional use in other applications, e.g., the replacement of asbestos in brake linings, healthy growth rates for aramids can be expected.

7. Economic Aspects

A breakdown of aniline consumption by region is given in Table 2.

Table 2. Aniline consumption by region

Region	Percentage of consumption
Europe	39 %
Americas	34 %
Asia	27 %

Much of the growth in demand for aniline in recent years has originated in Asia, where extensive use of MDI based polyurethanes in construction and consumer goods was the driver for the entire urethanes sector. A substantial part of Asia′s demand for urethanes and urethane raw materials, however, was imported from Europe and the United States. It is safe to say that Asia will see stronger growth in demand for aniline because major MDI producers are pushing ahead with plans to build large plants in the region.

World aniline production capacity was estimated at ca. 2.3×10^6 t for 1996. Capacity by geographic area in 10^3 t was:

Europe	960
Americas	820
Japan	270
Asia exc. Japan	250
Africa	7

In 1996 worldwide more than 40 companies produced aniline. The leading manufacturers were (capacity in 10^3 t):

ICI incl. joint ventures	460
Bayer	345
BASF incl. joint ventures	305
Mitsui	125
DuPont	118
First Chemical Corp.	131
Aristech	91
MCHZ	75
Anilina de Portugal	60

BASF was the sole company with production facilities in Europe, the United States, and Asia. Besides ICI and Bayer with sites in Europe and the United States all other companies were restricted to one region or one site only.

Expansions that have taken place since 1996 and formally announced projects taken into account, annual world capacity will grow to more than 3.50×10^6 t until 2005, with ICI and BASF leading the competition by a wide margin.

8. Derivatives

Table 3 shows substituted anilines, their properties, and their uses.

***o*-Chloroaniline** [*95-51-2*], 1-amino-2-chlorobenzene, $ClC_6H_4NH_2$, is a water-white to tan liquid, M_r 127.6, Tagliabue open cup (TOC) flash point 90 °C, *bp* 208 °C, *fp* −2.3 °C. *o*-Chloroaniline is *used* as an intermediate for rubber chemicals, pigments, pesticides, and dyes. *Production* is by low-pressure hydrogenation of 2-chloronitrobenzene with noble metal and/or noble metal sulfide catalysts at temperatures of ca. 50–100 °C in inert organic solvents. The yield is almost quantitative.

***m*-Chloroaniline** [*108-42-9*], 1-amino-3-chlorobenzene, $ClC_6H_4NH_2$, is a water-white to light-amber liquid, M_r 127.6, flash point (TOC) 90 °C, *bp* 230 °C, *fp* −10.5 °C. This compound is *used* as an intermediate for pesticides, pharmaceuticals, and dyes. It is *produced* by low-pressure hydrogenation of 3-chloronitrobenzene in the liquid phase with noble metal and/or noble metal sulfide catalysts. The addition of metal oxides to the reaction helps avoid dehalogenation. The yield is approximately 98 %.

***p*-Chloroaniline** [*106-47-8*], 1-amino-4-chlorobenzene, $ClC_6H_4NH_2$, is a white to light amber, crystalline solid at room temperature, M_r 127.6, *bp* 230 °C, *mp* 70 °C. It is *used* as an intermediate for pesticides, pharmaceuticals, pigments, and dyes. *Production* is similar to that of *m*-chloroaniline [31].

3,4-Dichloroaniline [*95-76-1*], 1-amino-3,4- dichlorobenzene, $Cl_2C_6H_3NH_2$, is a gray to dark-brown crystalline solid at room temperature, M_r 162.0, *fp* 66–71 °C, *bp* 272 °C. It is *used* as an intermediate for pesticides and dyes and is *produced* by catalytic hydrogenation of 3,4-dichloronitrobenzene with noble metal catalysts under pressure. Various types of additives prevent dehalogenation during production and reactors must be fabricated with special steel alloys to inhibit corrosion [31], [32].

***N,N*-Dimethylaniline** [*121-69-7*], *N,N*-dimethylphenylamine, $(H_3C)_2NC_6H_5$, is a light yellow (straw colored) to brown oily liquid, freezing to a crystalline solid at low temperatures, M_r 121.2, *fp* 2.1 °C, flash point, Tagliabue closed cup (TCC) 63 °C, *bp* 193 °C. It is *used* as a polymerization catalyst and as an intermediate for pharmaceuticals and dyes. Dimethylaniline is *produced* from aniline and methanol under pressure in the presence of acidic catalysts or by passing dimethyl ether and aniline vapor over

Table 3. Substituted anilines

Class and name	Formula	CAS registry number	M_r	Appearance [a]	*mp*, °C	*bp*, °C	d_4^{20} [b]	n_D^{20} [b]	Solubility [a]	Use [c]

highly activated aluminum oxide at 230 – 295 °C [33].

***N,N*-Diethylaniline** [*91-66-7*], *N*-phenyldiethylamine, $(H_5C_2)_2NC_6H_5$, is a yellow to brown, oily liquid, M_r 149.2, flash point (TOC) 85 °C, *bp* 216 °C. *Uses* are similar to those for the dimethyl analogue. Its *production* is analogous to methods used for dimethylaniline production except that ethanol instead of methanol is reacted with aniline.

***N*-Phenylacetamide** [*103-84-4*], acetanilide, acetylaniline, $C_6H_5NHCOCH_3$, is a colorless, glossy, crystalline material, M_r 135.2, *fp* 114 °C, *bp* 304 °C. It is *used* as a dye intermediate, plasticizer and stabilizer for cellulose esters, and as an intermediate for the synthesis of sulfonamides. It is *produced* by heating aniline with acetic acid, acetic anhydride, or acetyl chloride [34].

2,4-Xylidine [*95-68-1*], *m*-xylidine, 2,4-dimethylaniline, $(H_3C)_2C_6H_3NH_2$, is a colorless to tan, oily liquid, M_r 121.2, flash point (TCC) > 93 °C, *bp* 213 °C. It is *used* as an intermediate for photographic chemicals, pesticides, and dyes. It is *produced* by the catalytic hydrogenation of the corresponding nitro derivative.

2,6-Xylidine [*87-62-7*], 2,6-dimethylaniline, $H_2NC_6H_3(CH_3)_2$, is a colorless to reddish-yellow, clear liquid, M_r 121.2, flash point (TCC) > 94 °C, *bp* 217 °C. This compound is *used* as an intermediate for dyes, pesticides, and pharmaceuticals. *Production* is by the catalytic hydrogenation of the corresponding nitro derivative [35].

***N*-Phenylaminobenzene** [*122-39-4*], diphenylamine, $C_6H_5NHC_6H_5$, is isolated in the form of colorless leaflets, M_r 212.2, flash point (TCC) 153 °C, *bp* 302 °C, *mp* 53 °C. Diphenylamine is *used* as a stabilizer for elastomers, nitrocellulose, and nitroglycerine and as an intermediate for dyes. It is *produced* by passing aniline over various types of acidic catalysts at elevated temperatures and pressures [36].

9. Toxicology

9.1. Toxicokinetic Properties and Metabolism

Aniline, a weakly alkaline liquid, is readily absorbed into the circulation after oral ingestion, inhalation and dermal contact. In human volunteers, more than 90 % of the inhaled aniline vapors (5 – 30 mg/m^3) were absorbed in the state of rest [37–39]. The percutaneous uptake from the vapor phase accounted for 25 – 30 % of the total incorporation in normally dressed individuals at 25 °C and 35 % relative air humidity (estimated absorption rate: 0.2 – 0.4 µg cm^{-2}h^{-1}), but increased by 21 and 29 % when the temperature was elevated by 5 °C and the humidity from 35 to 75 %, respectively [38]. Likewise, when applied as liquid to human skin from a drained gauze (concentration 10 mg/cm^2), skin absorption of aniline was between 0.2 and 0.7 mg cm^{-2}h^{-1} but could reach up to 3.5 mg cm^{-2}h^{-1} on highly moistened skin [38], [39], also temperature appeared to be a factor.

Aniline undergoes rapid oxidation, mainly in the liver, but also in other organs like the intestine and erythrocytes. Three primary transformation reactions compete with each other and are expressed to varying degree in different species and individuals:

1) *N*-Hydroxylation
2) (Ring) hydroxylation
3) *N*-Acetylation followed by *p*-(ring) hydroxylation

In secondary steps, the hydroxyl intermediates are rapidly conjugated, largely to sulfate and glucuronic acid and excreted, mainly in the urine [40–43]. In humans, the half-life of aniline is ca. 3.5 h [39].

The primary conversion products, mainly phenylhydroxylamine and *p*-aminophenol as well as their oxidized forms nitrosobenzene and *p*-iminoquinone, resulting from reactions 1 and 2, are regarded as toxification steps to biologically active compounds (see below), whereas *N*-acetylation may be considered as a detoxification step, which is followed by *p*-hydroxylation to *N*-acetyl-*p*-aminophenol. *N*-Acetyl transferase is congenitally expressed to varying extent in humans ("strong and weak

acetylators"; see below); this is a reason for different individual susceptibilities.

Certain metabolites, such as nitrosobenzene, are coupled to thiols, especially glutathione; the quantities of aniline-protein conjugates, especially aniline-Hb adducts in blood, are diagnostic tools for the estimation of aniline exposure and body burden [44], [45].

9.2. Toxicological Properties

Central Nervous System Effects. Aniline may produce an euphoric state through its action on the central nervous system. At very high exposure, a narcotic effect may result and also cardiac dysfunction, coma, convulsions, and respiratory paralysis.

Methemoglobinemia and Hemolysis. Methemoglobinemia and hemolysis are typical aniline-related effects; they are frequently observed also with many other related aromatic amines: Primary oxidation products (phenyl hydroxylamine, *p*-aminophenol) are regarded as intermediate active agents and show in the presence of oxygen the propensity to compete with redox cycles (for a review see [46]).

Cats and humans appear to be the most responsive species and more susceptible than rats and mice [47–49]. In healthy adult humans, ca. 25 mg aniline per individual, orally ingested for 3 consecutive days, was found to be a critical threshold dose which causes measurable elevation of metHb; the highest noneffective dose in rats was reported as 20 mg/kg [50]. Up to ca. 15 % of metHb are normally tolerated in humans; doses of 65 mg per person may transiently exceed the 15 % limit [50].

One sequel of metHb formation may be the destruction and hemolysis of erythrocytes, associated with the formation of "Heinz bodies" in red blood cells and a hemolytic anemia with secondary effects on other organs.

A deficiency in oxygen supply follows the depletion of normal Hb to metHb and causes, depending on the dose, hypoxemia, anoxia, bluish discoloration to pronounced cyanosis, headache, weakness, drowsiness, shortness of breath, and unconsciousness.

In one acute case, a massive suicidal dose of 60 mL orally, the "hemolytic crisis" caused death by organ failure of heart, liver, kidney, and lung [51].

Early reports say that 6-h exposures to 40 – 53 mL/m^3 of aniline vapors (150 – 200 mg/m^3) were tolerated by workers without noticeable symptoms [52], but in other cases slight discomfort or dysfunction were produced already at 7 – 26 mL/m^3 after several hours; 105 – 160 mL/m^3 were not tolerable for more than 1 h without the health status being severely disturbed [52].

The ratio of toxifying and detoxifying reactions has implications for the individual susceptibility: ca. 50 % of Europeans are congenitally deficient in hepatic N-acyl transferase: in these individuals, the formation of inactive acetanilide is delayed in favor of phenylhydroxylamine and nitrosobenzene. Even at the industrial limit concentration of 2 mL/m^3, the sensitive persons show higher mean levels of metHb (1.5 versus 0.9 %) and of aniline-Hb adducts than similarly exposed persons with a high acetylating capacity [52, p. 7].

In general, methemoglobinemia will reverse spontaneously when exposure ceases. Cyanosis, however, needs medical treatment with supportive measures, e.g., oxygen inhalation and bed rest. In most cases, normal body functions will be restored after 3 weeks without irreversible damage [53].

Genotoxicity/Carcinogenicity. Under specific activating test conditions, aniline may exhibit certain forms of genotoxicity: standard Ames assays are negative, unless the incubation mixture is coactivated with norharmane. In mammalian cell assays for DNA damage, gene mutation and clastogenicity, and also in vivo, varying results were obtained. However, aniline does not appear to be a potent genotoxic agent [52].

In the early years of industrial production of aniline-based dyes, an increased incidence of urinary bladder cancer was ascribed to aniline exposure [54], [46]. However, it was recognized later that contaminations of β-naphthylamine or benzidine probably were the active agents, aniline itself was mainly considered noncarcinogenic.

Most early experimental investigations failed to support carcinogenicity (for a detailed review on early studies: see [59]. However,

in more recent rodent long-term feeding studies with aniline HCl, the incidence of spleen sarcomas was significantly increased in rats (100 – 300 mg $kg^{-1}d^{-1}$); the lower levels (10 – 30 mg $kg^{-1}d^{-1}$) were still associated with hemato- and splenotoxicity and few spleen tumors [55–58]. It was therefore assumed that the production of spleen sarcomas was a secondary response, initiated by the hemolytic toxicity and associated with the decay and phagocytosis of damaged erythrocytes in spleen sinuses, including an iron overload in this target organ. This is supported by the fact that the spleen is a very unique target organ for carcinogenic effects even with strongly genotoxic compounds, whereas spleen enlargement, hemosiderosis (iron deposition) and splenic lipid peroxidation [47] are typically induced by aniline-related methemoglobinemia. Tumorigenesis of typical genotoxic aromatic amines (→ Amines, Aromatic, Chap. 5.1.) is usually seen at other tumor sites than spleen [52].

Studies of individuals exposed to aniline and not to other aromatic amines have shown little evidence of increased tumor risk: among 1223 men producing or using aniline one bladder cancer was recorded vs. 0.83 expected from the general population incidence [59].

Reproduction Toxicity. Although aniline can pass the placental barrier, studies in rats and mice failed to provide evidence for the induction of malformations in the fetus. Slight embryo retardations, fetal hematological effects, and increased liver weights were recorded at the highest dose of 100 mg kg^{-1} d^{-1}. Also maternal effects occurred at that level. The no observed effect level was 10 mg kg^{-1} d^{-1} [60–62].

10. Occupational Health

Based on absorption properties (see Chap. 9), a TLV and a MAK value (maximal concentration at the workplace) of 2 ppm (8 mg/m^3) with a skin notation (potential of toxicologically relevant cutaneous absorption) were established in the United States and Germany, respectively [63], [52].

In Germany, because of the limited data base for embryotoxicity, the MAK Commission has allocated aniline to group D (no final conclusion on the prenatal risk under MAK value conditions) [52].

1. Introduction

Anorexiants are substances that depress the desire for food. They are also referred to as anorectic agents, anorexigenics, and appetite suppressants. Because the main therapeutic use of these substances is to control weight, they are also called antiobesity agents. This term, however, is too broad when only the suppression of the desire for food is meant, for antiobesity drugs include not only anorexiants but also metabolism and biosynthesis modifiers [1].

The control of weight or obesity by drug therapy rather than dieting alone remains controversial because of the potential health risks and the limited efficacy of most of the available drugs. However, because many people find dieting difficult and seek some supportive measure, the use of drugs in a reducing program as an adjunct to diet modification and exercise is well established. A report on obesity in the United Kingdom [2] documents the adverse effects of obesity when coupled with such medical problems as coronary heart disease, hypertension, diabetes, gall bladder disease, respiratory disease, varicose veins, and certain forms of cancer.

2. Animal and Human Test Procedures

The main techniques used to search for anorexiants in animal models are the free feeding and operant behavioral methods [3]. Both measure the effectiveness of a compound at reducing food consumption in animals made hungry by dietary restrictions.

In the *free feeding* procedure the food intake is measured over a period of time. The animals then are given a drug and the effect on food intake is determined. Agents that reduce intake are potential anorexiants. Because this technique cannot distinguish true anorectic effects from conflicting pharmacologic properties, more refined models involving measurement of *operant behavior* have been designed. Animals are trained to respond to a food presentation by lever pressing, runway performance, and various shock schedules [4]. These methods have verified anorectic efficacy in a number of phenethylamine derivatives but are less successful in defining unique compounds with confirmed activity in humans [5].

Human testing of potential anorexiants involves measuring weight loss after drug therapy has been initiated. In addition the measurement of the thickness of the underarm skin-fold and subjective reports from the patient regarding desire for food also are used frequently. Despite many clinical references on anorectic agents, a standard testing procedure has not yet been designed [6].

3. Mechanism of Action

The regions of the brain that are involved in central control of appetite are thought to be mainly in the hypothalamus. Control of food intake is considered to involve a feeding center and a satiety center. Electrical stimulation of the ventrolateral hypothalamus causes feeding in sated animals; whereas stimulation of the ventromedial hypothalamus inhibits ongoing feeding [7], [8].

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a02_313

At the molecular level a multiplicity of neurotransmitters are involved in the control of appetite. These substances can be classified broadly as neuropeptides and monoamines, with the latter class being investigated the most. The satiety and feeding centers appear to be controlled mainly by norepinephrine [*51-41-2*] and serotonin [*50-67-9*].

Norepinephrine

Serotonin

Commercial anorectic agents all appear to operate through a mechanism that involves the control of reuptake or release of these monoamines from the appropriate area of the hypothalamus [8], [9].

4. Clinical Side Effects

The drugs used to control appetite are taken orally one to three times daily, usually before meals. Medical practice in the United States calls for a maximum usage of twelve weeks; the majority of drugs appear to lose effectiveness after this time [10]. Because the neurotransmitters that control appetite also are involved in other biochemical pathways, drugs that affect them give rise to a variety of side effects. These side effects can be grouped into four major categories:

– Central nervous system (CNS)
– Cardiovascular
– Gastrointestinal
– Abuse and/or dependence

All the anorectic drugs except fenfluramine excite the *central nervous system* and give rise to restlessness, insomnia, tremor, euphoria, and headache. *Cardiovascular problems* include elevated blood pressure, palpitations, and rapid heart action (tachycardia). *Gastrointestinal irritation* can cause nausea, vomiting, dry mouth, unpleasant taste, diarrhea, and constipation.

Abuse and dependence of a physiologic or psychological origin are a particular problem with those compounds closely related to amphetamine. Symptoms of chronic abuse include prolonged insomnia, severe skin diseases, baldness, and dramatic personality changes resulting in schizophrenia-like behavior. Withdrawal by addicted patients is characterized by profound fatigue and mental depression. The seriousness of the abuse and dependency with these drugs has led various United States regulatory agencies to control them under the Bureau of Narcotics and Dangerous Drugs (BNDD). To assist the physician the drugs have been classified under BNDD Schedules I – IV, with Schedule IV substances being the least prone to cause abuse and dependency problems [11].

5. Phenethylamine Derivatives

The β-phenethylamine framework is found in all but one of the clinically useful anorectic drugs. This same unit is also found in the neurotransmitter

norepinephrine (see Chap. 3). Modification of the molecule by introducing one or two methyl groups in the α position has led to the β-phenylisopropylamines (Section 5.1) and β-phenyl-*tert*-butylamines (Section 5.2). Additional modification at the β position with a hydroxyl or ketone group gives the β-phenyl-β-oxyisopropylamines (Section 5.3), and cyclization of the oxygen and nitrogen atoms by a two-carbon bridge results in the 1-methyl-2-phenylmorpholines (Section 5.4). The (+) isomer of those compounds containing a chiral α carbon atom is the more active anorectic agent. Extensive studies have demonstrated that a Cl or CF_3 group in the ring or a group on the nitrogen atom that can be metabolized to the NH_2 derivative gives rise to clinically useful drugs [12].

The first phenethylamine derivative to be used as an anorexiant was ($\pm$)-amphetamine [13]. Subsequently, studies showed that the (+) isomer, dextroamphetamine, has fewer side effects and it has become used more widely. Combinations of phenethylamines with sedatives and tranquilizers have been prescribed in an attempt to alleviate the undesirable stimulant effects. Slow-release and resin-bound forms also have been marketed to overcome the same problem.

5.1. β-Phenylisopropylamines

Drugs containing β-phenylisopropylamine or its structural framework constitute the largest group of anorexiants on the market.

The general procedure for preparing these compounds involves reaction of a phenylacetone with hydroxylamine followed by catalytic hydrogenation, or reaction of the ketone with formamide (Leuckart-Wallach reaction) and subsequent acid hydrolysis (Eq. 1).

The *N*-alkyl derivatives are made by reductive aminoalkylation of phenylacetone by catalytic hydrogenation (Eq. 2). The optically active forms can be obtained by resolution with an optically active acid or by starting with (+)- or (-)-ephedrine, conversion to a chloroamine, and then catalytic hydrogenation (Eq. 3).

Amphetamine [*300-62-9*], benzedrine, (±)-α-methylbenzeneethanamine, $R^1 = R^2 = H$, $C_9H_{13}N$, M_r 135.21, is a colorless liquid, *bp* 200 – 201 °C; hydrochloride, *mp* 148 – 149 °C.

Amphetamine is prepared by treating phenylacetone with formic acid and ammonia under the Leuckart-Wallach conditions (Eq. 1) [14].

Trade names: Benzedrine (SKF), Obetrol-10 and Obetrol-20 (combined with dextroamphetamine; Schein), Biphetamine (resin combined with dextroamphetamine, Pennwalt), all United States; Adiparthrol (Medial, Switzerland).

Recommended adult dosage is 10 – 30 mg/d; BNDD Schedule II (United States).

Dextroamphetamine [*51-64-9*], (+)-α-methylbenzeneethanamine, $R^1 = R^2 = H$, $C_9H_{13}N$, M_r 135.21, is a colorless liquid, *bp* 80 °C (1.6 kPa), $[\alpha]_D^{15}$ +35.6° (neat); 0.5 sulfate, *mp* > 300 °C, $[\alpha]_D^{20}$ +21.8 to 24° (*c* = 5 g/100 mL H_2O).

The compound can be prepared by optical resolution of amphetamine (see above) or directly from (-)-norephedrine by conversion to the (+)-chloroamine followed by catalytic hydrogenation (Eq. 3) [14].

Trade names: Dexedrine (SKF, United States, Federal Republic of Germany, Switzerland), Obetrol-10 and Obetrol-20 (combined with amphetamine; Schein, United States).

Recommended adult dosage is 10 – 30 mg/d; BNDD Schedule II (United States). Dextroamphetamine also is approved for use in narcolepsy and for control of hyperkinetic children [15].

Methamphetamine [*537-46-2*], desoxyephedrine, *S*-(+)-*N*, α-dimethlybenzeneethanamine, $R^1 = H$, $R^2 = CH_3$, $C_{10}H_{15}N$, M_r 149.24; hydrochloride, *mp* 171 – 175 °C, $[\alpha]_D^{20}$ +16.0 to 19.2° (*c* = 5 g/100 mL H_2O) is prepared from phenylacetone and methlyamine (Eq. 2) or from (-)-ephedrine (Eq. 3) [16].

Trade names: Desoxyn (Abbott), Obedrin (Beecham-Massengill), both United States; Pervitin (Temmler-Werke, Federal Republic of Germany).

Recommended adult dosage is 7.5 – 15 mg/d; BNDD Schedule II (United States).

Benzphetamine [*156-08-1*], (+)-*N*,α-dimethyl-*N*-(phenylmethyl)benzeneethanamine, $R^1 = CH_3$, $R^2 = C_6H_5CH_2$, $C_{17}H_{21}N$, has M_r 239.35, *bp* 127 °C (3.5 Pa); hydrochloride, *mp* 129 – 130 °C, $[\alpha]_D^{20}$ +22 to 26° (*c* = 5 mg/100 mL H_2O).

Benzphetamine can be prepared by treating methamphetamine (see above) with a benzylhalide in the presence of a base [17].

Trade names: Didrex (Upjohn, United States, United Kingdom), Inapetyl (Upjohn, France).

Recommended adult dosage is 25 – 150 mg/d; BNDD Schedule III (United States).

Fenfluramine [*458-24-2*], *N*-ethyl-α-methyl-3-(trifluoromethyl)benzeneethanamine, $R^1 = H$, $R^2 = C_2H_5$, 3-CF_3, $C_{12}H_{16}F_3N$, has

M_r 231.27, *bp* 108 °C (1.7 kPa); hydrochloride, *mp* 166 °C.

Fenfluramine is prepared by reductive alkylation of norfenfluramine with acetaldehyde [18]. The nor compound is obtained by catalytic hydrogenation of the oxime made from 3-trifluoromethylphenyl acetone (Eq. 2).

Trade names: Pondomin (Robbins, United States), Ponderal (Servier, France), Ponderax (Boehringer Ingelheim, Federal Republic of Germany).

Recommended adult dosage is 60 mg/d; BNDD Schedule IV (United States).

Fenfluramine is the only marketed anorectic agent that exerts its appetite depressant effect via a serotoninrgic mechanism (see Chap. 3). Its major metabolite, norfenfluramine, is believed to be the main active form in humans [19].

Propylhexedrine [*101-40-6*], cyclexedrine, *N,α*dimethylcyclohexaneethanamine, $C_{10}H_{21}N$, has M_r 155.28, *bp* 92 – 93 °C (2.7 kPa); (-)-hydrochloride, *mp* 138 – 140 °C, $[\alpha]_D^{20}$ −14.2° (H_2O); (±)-hydrochloride, *mp* 127 – 128 °C.

Propylhexedrine is prepared by catalytic hydrogenation of (±)- or (-)-ephedrine in a strong mineral acid [20].

Trade names: Eventin [(-) isomer, Chemische Werke Minden]; Eggobasin, [(±) isomer, Fahlberg-List]; both Federal Republic of Germany.

The compound is marketed in the United States as an inhalant for nasal congestion and not as an anorectic agent.

5.2. β-Phenyl-*tert*-butylamines

The β-phenyl-*tert*-butylamines appear to offer no advantages over the β-phenylisopropylamines (Section 5.1). These *tert*-butylamines are known to induce pulmonary hypertension and their use in medical practice is declining.

Phentermine [*122-09-8*], α,α-dimethylbenzeneethanamine, $C_{10}H_{15}N$, M_r 149.23, is a colorless liquid, *bp* 100 °C (0.36 kPa); hydrochloride, *mp* 198 °C.

Phentermine is prepared by converting the condensation product of benzaldehyde and nitropropane to the corresponding aminoalcohol followed by transformation to the chloroamine and then catalytic hydrogenation (as in Eq. 3) [21].

Trade names: Ionamin (resin; Pennwalt), Fastin (Beecham), Adipex (Lemmon), Oby-Trim (Obetrol), Teramine (Legere), Phentermine (Schein, Rugby), all United States.

Recommended adult dosage is 20 – 40 mg/d; BNDD Schedule IV (United States).

Phentermine has not been marketed in the Federal Republic of Germany since 1968 because of suspected pulmonary hypertension.

Phenpentermine [*434-43-5*], pentorex, α, α,β-trimethylbenzeneethanamine, $C_{11}H_{17}N$, has M_r 161.35; hydrochloride, *mp* 164 – 166 °C; hydrogen tartrate [*22876-60-4*], *mp* 160 – 162 °C, $[\alpha]_D^{20}$ +13.4° (c = 0.8 g/100 mL H_2O).

Phenpentermine is prepared by *N*-formylating the alcohol obtained from 3-phenyl-2-butanone and methylmagnesium bromide; the intermediate is hydrolyzed in acid [22].

Trade name: Modatrop (Nordmark Werke, Federal Republic of Germany).

5.3. β-Phenyl-β-oxyisopropylamines

These drugs are the safest and most widely used anorexiants on the market.

Ephedrine [*299-42-3*], (-) isomer, [*R*-(*R*∗, *S*∗)]-α-[1-(methlyamino)ethyl]benzenemethanol, A = HCOH, R^1 = H, R^2 = CH_3, $C_{10}H_{15}NO$, has M_r 165.23, *mp* 33 – 39 °C; hydrochloride [*50-98-6*], *mp* 217 – 220 °C, $[\alpha]_D^{20}$ −34.0 to −35.0 °(c = 5 g/100 mL H_2O).

(-)-Ephedrine is obtained by the catalytic hydrogenation of (-)-1-phenyl-2-methlyaminopropan-1-one. The latter substance is prepared by the optical resolution of the (±)-ketoamine [23].

Ephedrine

Trade name: Alfabet (Zeppenfeldt, Federal Republic of Germany).

Norephedrine [*14838-15-4*], phenylpropanolamine (PPA), (*R*∗,*S*∗)-(±)-α-(1-aminoethyl)benzenemethanol, A = HCOH, R^1 = R^2 = H, $C_9H_{13}NO$, has M_r 151.18; hydrochloride [*154-41-6*], *mp* 190 – 194 °C.

Phenylpropanolamine is prepared by converting propiophenone to the α-oximino derivative with an alkyl nitrite, followed by catalytic hydrogenation, using a Pd or Pt catalyst [24].

Phenylpropanolamine

Phenylpropanolamine is the only FDA approved (1978) appetite suppressant that is sold without a prescription on the United States market. In 1983, there were 35 brands of PPA available as a single drug entity (100 – 150 mg) or mixed with the central nervous system stimulant caffeine (50 – 200 mg), with the local anesthetic benzocaine, or with such bulk products as methyl or carboxymethlycellulose. Because PPA is so widely available, it has been abused, necessitating tighter controls on availability [25]. Phenylpropanolamine also has been used medically since the 1950s, primarily as a nasal decongestant and ingredient in cold remedies.

Norpseudoephedrine [*492-39-7*], [*36393-56-3*], cathine, (+) isomer, [*R*-(*R*∗,*R*∗)]-α-(1-aminoethyl)benzenemethanol, A = HCOH, R^1 = R^2 = H, $C_9H_{13}NO$, has M_r 151.18, *mp* 77 – 79 °C; hydrochloride *mp* 180 – 182 °C, $[\alpha]_D^{20}$ +42.5 to 44.0 ° (c = 5 mg/100 mL H_2O).

(+)-Norpseudoephedrine can be obtained by resolving the (±) form with d-mandelic acid or by isomerization of (-)-norephedrine [26].

Trade names: Adiposetten (Reiss), Boxogetten (Boxberger), both Federal Republic of Germany; Minusin (Doetsch-Grether, Switzerland).

Diethylpropion [*90-84-6*], amfepranon, α-(diethylamino)-phenyl-1-propanone, A = CO, R^1 = R^2 = C_2H_5, $C_{13}H_{19}NO$, has M_r 205.30, *bp* 140 °C (0.1 kPa); hydrochloride [*134-80-5*], *mp* 172 – 176 °C.

Diethylpropion is prepared by α-bromination of propiophenone followed by reaction with diethylamine [27].

Diethylpropion is the anorectic prescription drug of choice in the United States. It possesses central nervous system stimulant effects that are considerably weaker than those of amphetamine and its close analogs. Drug abuse and dependence is also low with diethylpropion.

Trade names: Tenuate (Merrell Dow, United States, Federal Republic of Germany, United Kingdom), Regenon (Temmler Werke, Federal Republic of Germany), diethylpropion HCl (Schein, Rugby, United States), Tepanil (Riker, United States).

Recommended adult dosage is 75 mg/d; BNDD Schedule IV (United States).

5.4. 1-Methyl-2-phenylmorpholines

The clinical side effects and efficacy of the 1-methyl-2-phenylmorpholines are similar to those of the amphetamines, and the probability of drug abuse is quite high.

All of these anorectics exist as *threo* isomers.

Phenmetrazine [*134-49-6*], *trans*-3-methyl-2-phenylmorpholine, R = H, $C_{11}H_{15}NO$, has M_r 177.50, *bp* 138 – 140 °C (0.04 kPa); hydrochloride [*1707-14-8*], *mp* 182 °C.

Phenmetrazine is prepared by reacting α-bromopropiophenone with *N*-benzylethanolamine, catalytic reduction of the intermediate ketone to *N*-hydroxyethyl norephedrine or norpseudoephedrine, and then cyclization with concentrated sulfuric acid [28].

Trade names: Preludin (Boehringer-Ingelheim, United States), Cafilon [in combination with 8-chlorotheophyllinate and phenbutrazate (see below), Ravensberg, Federal Republic of Germany].

Recommended adult dosage is 50 – 75 mg/d; BNDD Schedule II (United States).

Phendimetrazine [*634-03-7*], *L*-(+)−3*R*-*trans*-3,4-dimethyl-2-phenylmorpholine, R = CH_3, $C_{12}H_{17}NO$, has M_r 191.26, *bp* 134 – 135 °C (0.21 kPa); hydrochloride, *mp* 208 °C, $[\alpha]_D^{20}$ + 35.7 ° (H_2O); hydrogen tartrate [*50-58-8*].

The compound can be prepared by the same procedure used to prepare phenmetrazineexcept that *N*-methlyethanolamine is reacted with α-bromopropiophenone [29].

Trade names: Plegine (Ayerst), Prelu-2 (Boehringer-Ingelheim), Bontril (Carnrick), Melfiat (Reid-Provident), all United States.

Recommended adult dosage is 30 mg/d; BNDD Schedule III (United States).

Phenbutrazate [*4378-36-3*], α-ethyl-2-(3-methyl-2-phenyl-4-morpholinyl)ethyl ester benzeneacetic acid, R = $CH_2CH_2OCOCH(C_2H_5)C_6H_5$, $C_{23}H_{29}NO_3$, has M_r 367.47; hydrochloride [*6474-85-7*], *mp* 154 °C.

Phenbutrazate is prepared by condensing *N*-hydroxyethylphenmetrazine (R = CH_2CH_2OH) with 2-phenylbutyric acid. The *N*-hydroxyethyl compound is obtained in the same manner as phendimetrazine [30].

Trade name: Cafilon [in combination with 8-chlorotheophyllinate and phenmetrazine (see above), Ravensberg, Federal Republic of Germany].

6. Other Compounds

A variety of compounds that do not possess the phenethylamine framework has been studied as anorectic agents; to date, however, only mazindol has reached the marketplace [12].

Mazindol [*22232-71-9*], 5-(4-chlorophenyl)-2,5-dihydro-3*H*-imidazo[2,1-*a*]isoindol-5-ol, $C_{16}H_{13}ClN_2O$, has M_r 284.74, *mp* 198 – 199 °C.

Mazindol is prepared by treating the dilithio reagent, obtained from 2-phenylimidazoline, with methyl 4-chlorobenzoate [31].

Although mazindol is unrelated structurally to the phenethylamine anorectic agents, it possesses a similar medical profile in humans. The most common side effects observed are dry mouth, tachycardia, constipation, nervousness, and insomnia. The mechanism responsible for the anorectic effects of mazindol differs from that for amphetamine and probably involves effects on both norepinephrine and serotonin [32].

Trade names: Sanorex (Sandoz), Mazanor (Wyeth), both United States; Teronac (Wander, Federal Republic of Germany).

Recommended adult dosage is 2 – 3 mg/d; BNDD Schedule IV (United States).

Table 1. Sales of prescription anorexiants on the United States market between October 1983 and October 1984

Anorexiant (BNDD schedule)	Trade name(s)	Sales, $\$ \times 10^3$	% of Market
Phentermine (IV)	Ionamin, Fastin, Adipex-P, generic	27868	36.7
Diethylpropion (IV)	Tenuate, Tepanil, generic	17970	23.7
Benzphetamine (III)	Didrex	7282	9.6
Phendimetrazine (III)	Prelu-2, Melfiat, Plegine, Bontril, generic	4899	6.5
Phenmetrazine (III)	Preludin	3977	5.3
Methamphetamine (II)	Desoxyn	3681	4.9
Mazindol (IV)	Sanorex, Mazanor	2928	3.9
Dextroamphetamine and amphetamine (II)	Biphetamine	2919	3.9
Dextroamphetamine (II)	Dexedrine	2858	3.9
Fenfluramine (IV)	Pondimin	393	0.4

7. Economic Aspects

The total sales of prescription anorexiants in the United States between October 1983 and October 1984 were $ 76 188 000. Products containing anorexiants classified as BNDD Schedule III or IV accounted for 82.3 % of the sales, while the more restricted drugs of Schedule II totaled 17.7 %. Table 1 gives United States sales figures for individual prescription anorexiants [33].

1. Introduction

Acid-related diseases of the upper gastrointestinal tract (GI-tract) comprise all the diseases of the esophagus, stomach, and duodenum that can be beneficially affected by neutralizing gastric acid or by inhibiting its secretion. These diseases include gastroesophageal reflux disease (GERD) [1], gastritis [2], gastric and duodenal ulcers (GU and DU [3]), drug-induced ulcers [4], Zollinger – Ellison syndrome [5], and stress ulcers [6]. However, "acid related" does not mean that all these diseases are causally related to acid hypersecretion. They may in fact go along with normal or even subnormal acid secretion. The complex pathophysiology is based on an imbalance between aggressive and defensive factors and will be discussed in Chapter 2.

Acid-related disorders of the GI-tract still constitute a major national-economical issue in western countries. The "crude lifetime ulcer prevalence" has been estimated in the United States to be between 8 and 30 % [7]. This principal notion also applies to Germany where, in 1995, 239×10^6 daily doses of antiulcer drugs [H_2-receptor antagonists (H_2-RAs), proton pump inhibitors (PPIs), etc.] were prescribed [8]. Three major risk factors for peptic ulcers and related disorders have been identified by Kurata and Nogawa [9]: infection by *Helicobacter pylori* (H.p.), use of nonsteroidal antiinflammatory drugs (NSAIDs) such as diclofenac, and cigarette smoking. H.p. infection is predominantly acquired in childhood, but the incidence of infections during childhood was considered to have decreased over the past decades being in line with a cohort phenomenon [10], [11]. Thus, as far as peptic ulcers caused by H.p. infection are concerned, their prevalence was expected to decrease in the future because transmission should become less likely under improved hygienic conditions in industrialized countries [12]. On the other hand, Hornemann et al. [13] found an age-dependent increase in the prevalence of H.p. infection in healthy German children between birth and 17 years of age admitted to hospital for minor surgical procedures in 1983 and 1984. Consequently, these authors questioned a hygiene-related cohort effect and interpreted their data as possibly pointing to an oral-oral route of infection as opposed to a fecal-oral route.

2. Pathophysiology and Therapeutic Concepts

Although the dictum "no acid – no ulcer" [14] is still valid in the majority of peptic ulcer cases,

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a02_321

nowadays much more is known about their complex etiology and pathophysiology [15]. In fact, gastric acid and pepsin are the most important aggressive factors acting in concert with toxic factors of H.p. or with either NSAIDs, stress or smoking, but they are physiologically counterbalanced by defensive factors such as mucus and bicarbonate, epithelial cell lining and repair mechanisms, and mucosal blood flow [15], [16]. Consequently, although inhibition of acid secretion will be therapeutically effective even in cases with normal acid secretion, eradication of H.p. by antibiotics or improvement of mucosal defense, for example, by sucralfate and antacids, will either eliminate H.p. as the cause of the disease, or shift the balance in favor of defensive factors. Bismuth compounds do a little of both. Prostaglandin (PG) derivatives help preventing NSAID-induced ulcers by "gastroprotective" (misleadingly also called "cytoprotective") mechanisms but heal peptic ulcers only when given in antisecretory doses [17], [18]. Ulcer pain may be triggered by exposure of the inflamed mucosa to gastric acid [19] and will therefore be alleviated by antisecretory or acid-neutralizing drugs, apart from their healing effect.

The most effective target of acid-inhibitory drugs is the H^+/K^+-ATPase (acid pump; proton pump) of the parietal cell's apical membrane [20]. PPIs (pantoprazole, omeprazole, lansoprazole, see Section 3.1) block the final step in acid production (Fig. 1) and therefore display a higher antisecretory efficacy and clinical reliability than H_2-RAs (see Section 3.2) or, even more so, M_1-antimuscarinics. H_2-RAs block receptors for histamine located upstream on the basolateral membrane of the parietal cell (H_2-receptor), M_1-antimuscarinics block receptors for actetylcholine on either the histamine-liberating ECL-cell or intramural neurons (M_1-receptors). Consequently, both of these leave other pathways of acid stimulation unaffected. The only antimuscarinic antiulcer drug still in use is pirenzepine (see Section 3.4.3) which seems outdated due to its comparatively low efficacy combined with unwanted effects. Antacids (see Section 3.3), PG derivatives (see Section 3.4.1), sucralfate (see Section 3.4.4) and bismuth compounds (see Section 3.4.5) display complex actions partially related to acid, mucosal defensive mechanisms, and H.p. (see Section 4.2). Figure 1 provides an overview. Finally, the prokinetic drugs cisapride, metoclopramide, and domperidone facilitate propulsive motility of the GI-tract thus enhancing oral to aboral movement of contents to prevent duodeno-gastric reflux of bile acids or gastro-esophageal reflux of gastric acid (see Section 3.4.2).

3. Drugs

This section lays special emphasis on proton pump inhibitors as these drugs represent the latest development in the antisecretory therapy of peptic ulcer disease, succeeding H_2-receptor antagonists. In general, information on chemical and pharmaceutical drug properties, synonyms, trade names, dosages etc. beyond the information given below may be obtained from [22–26]. In the following sections, the chemical names of individual drugs are indicated according to the WHO nomenclature.

3.1. Proton Pump Inhibitors

Chemically, proton pump inhibitors (PPIs) consist of a substituted benzimidazole moiety linked by an essential sulfinylmethyl group to a substituted pyridine ring [20], [27]. They are acid-labile prodrugs that have first to be activated by acid in order to gain pharmacological activity but will subsequently be degraded to inactive products (see below). They are therefore administered as enteric-coated formulations (which protects the prodrug from acid in the gastric lumen), become absorbed from the intestine and penetrate into the acid compartment of the gastric parietal cell from the blood. The pH in the order of 1 present inside the canaliculus of a secreting parietal cell [20] causes protonation of the pyridine nitrogen (pK_a about 4) and thereby drug accumulation by a factor of more than 1000 relative to the blood. This protonation goes along with a complex, intramolecular rearrangement of the prodrug structure to form a thiophilic cyclic sulfenamide. The latter is a highly reactive compound and would be further degraded to inactive products (see above) if it were not generated in the vicinity of the extracytoplasmic portion of the proton pump where it immediately and covalently reacts with thiol groups of

Figure 1. Simplified and incomplete illustration of the interplay between various aggressive and defensive gastric mucosal factors, their physiological regulation, and the different drug targets in peptic ulcer therapy.
ACh = acetylcholine; ECL = enterochromaffine-like; G = gastrin receptor; Hist = histamine; H_2 = histamine H_2 -receptor; M_1 = muscarinic M_1 -receptor; N = nicotinic receptor; NSAIDs = nonsteroidal antiinflammatory drugs; PG = prostaglandin receptor.
X indicates inhibition of the respective target.
After BRUNTON [21], slightly modified.

the proton pump. The result is a mixed disulfide of the active drug and the enzyme protein [28], [29]. The disulfide structure arrests the catalytic cycle of the proton pump [20] and thus inhibits acid secretion. Although this constitutes an irreversible mode of inhibition in a chemical sense, acid inhibition by PPIs is biologically reversible due to the turnover of both the proton pump ($t_{1/2}$ approx. 72 or 54 h for the rat proton pump or its alpha subunit; [30], [31]) and the parietal cell (turnover time in the rat ca. 164 d [32]).

It has been estimated that about one-third of the parietal cell mass is in its resting state even during meal stimulation [33] and therefore not available for inhibition by PPIs [34]. These resting cells are liable to endogenous stimulation after the drug has been eliminated from blood circulation and thus mainly determine the recovery of acid secretion following a first drug administration. It also follows that PPIs achieve their steady state effect only over about 3 days of daily administration, and any co-administration of receptor antagonists (be it H_2- or M_1-blockers) with PPIs is contraindicated. In fact, the latter would lose instead of gain efficacy because receptor blockade would prevent a certain percentage of parietal cells from being stimulated for acid secretion thus kept in a resting state not allowing for PPI activation.

Cyclic sulfenamides generated by acid from the inactive prodrugs (for review, see [27]) are specific SH-reagents which can modify any thiol group and should therefore be prevented from unwanted reactions at any targets apart from the parietal cell's proton pump in order to avoid side effects as much as possible. Thus, the main aspect governing selection of candidate compounds during drug development was their pH-dependent activation profile. As discussed in detail by KROMER et al. [37], PPIs should be acid-activated as fast as possible at low pH values of about 1 in order to potently inhibit the pari-

etal cell's proton pump. However, they should be activated as slowly as possible at pH values well above 3 to avoid unwanted SH-reactions in moderately acidic tissue compartments like lysosomes and other acidic vesicles. "Fast" and "slow" activation is always meant relative to the serum elimination half-life $t_{1/2}$. For example, omeprazole is as quickly activated at pH 5 (where activation is unwanted) as it is eliminated from serum ($t_{1/2}$ approx. 1 h), whereas the PPI pantoprazole is eliminated from blood by a factor of about 3 faster than it is activated at pH values in the order of 5 [37]. For lansoprazole and rabeprazole, see [35], [36]. All of these drugs are acid-activated at pH 1 with activation half-lifes in the order of a few minutes compared to their serum elimination half-lifes of about 1 hour. They all display therefore similar antisecretory potencies and efficacies [38–44] which solely depend on the activation rate within the acid space of the parietal cell. For the same reason, 20 mg omeprazole achieved lower healing rates than 40 mg of either omeprazole or pantoprazole in a number of studies [45–51]. This data does not conflict at all with the failure of other studies [52], [53] to statistically distinguish 40 mg pantoprazole from 20 mg omeprazole since the two doses represent the upper part of the dose – response relationship. Consequently, they are separated by only a small (but clinically relevant) difference in healing rates confounded by comparatively large variations between different patient samples. It has therefore been judged from a medical rather than a statistical point of view that 20 mg omeprazole daily being underdosed and 40 mg daily of both omeprazole and pantoprazole being the correct and desirable dose for acute ulcer healing [54], [55]. Figure 2 demonstrates the congruence between animal data, human pharmacology data, and selected clinical data (see above) and shows the equipotency and equiefficacy of pantoprazole compared to omeprazole on a milligram basis.

A further goal pursued during selection of PPIs was to minimize potential interactions with cytochrome P450 in order to avoid unwanted drug interactions in the liver. Following phase I oxidation in the endoplasmic reticulum of the liver cell, pantoprazole undergoes cytosolic phase II sulfate conjugation which is independent of cytochrome P450 and not subject to drug interactions [57]. By contrast, phase II conjugation is lacking in case of omeprazole, which in addition has an about seven-fold higher affinity to human cytochrome P450 than pantoprazole [58]. The two differences, i.e., lower affinity to cytochrome P450 and phase II conjugation of pantoprazole as opposed to omeprazole explain well that pantoprazole did not display any metabolic drug interactions in man [59], [60], whereas omeprazole did in a number of studies [61–70], for review, see [71].

Another goal considered during PPI selection and development was to obtain linear pharmacokinetics both with respect to dose increments and repeated dosing over time. This goal has been achieved with pantoprazole [72–74] but not with omeprazole [75].

All of the differences in the aforementioned drug properties depend on the different substitution patterns of the two ring systems of the PPIs (Table 1). Regarding the pH-selectivity in the PPI's chemical activation (see above), "the difluoromethoxy group present in pantoprazole slows reaction at neutral pH by electron withdrawal, which decreases the pK_a of the benzimidazole N and reduces its protonation at all but highly acidic pH values" [20]. The higher lipophilicity of omeprazole explains its higher volume of distribution (i.e., a higher percentage shifted from serum into tissues) and, consequently, its somewhat lower maximum serum concentration (C_{max}) and area under the serum concentration – time curve (AUC) (→ Pharmaceutical Dosage Forms, Chap. 1. on bioavailability) compared to the same dose of pantoprazole [37], [76]. The biological implications of these differences have been discussed in [37]. The individual PPIs will be presented below in alphabetical order.

Table 1. Chemical structures of four proton pump inhibitors

Lansoprazole

Omeprazole

Pantoprazole

Pariprazole/Rabeprazole/E3810

Lansoprazole [*103577-45-3*], 2-[[[3-methyl-4-(2,2,2-trifluoroethoxy)-2-pyridyl]-methyl]sulfinyl]benzimidazole (WHO), $C_{16}H_{14}F_3N_3O_2S$, M_r 369.37 [77], available as capsules containing either 15 or 30 mg (free acid) of the racemic mixture (chiral center at the asymmetric sulfinyl group). Both the (+)- and (−)-enantiomers of lansoprazole are converted to the optically inactive cyclic sulfenamide and are therefore of the same antisecretory potency in vitro [78].

Trade names: Agopton (Takeda) and in addition various licensed products under different trade names (see [23]).

Omeprazole [*73590-58-6*], 5-methoxy-2-[[(4-methoxy-3,5-dimethyl-2-pyridyl)methyl]-sufinyl]benzimidazole (WHO), $C_{17}H_{19}N_3O_3S$, M_r 345.42 [52], available as capsules containing either 10, 20, or 40 mg and as a lyophylisate for i.v. infusion containing 40 mg of the racemic mixture (40 mg being equivalent to 42.6 mg of the sodium salt). The omeprazole enantiomers can be separated but both of them display about the same antisecretory potency in vitro [79], [80].

Trade names: The racemic mixture is produced by Astra/Hässle under trade names Antra and Losec, and is in addition distributed by various licensees under different trade names (see [23]).

Omeprazole was the first PPI in clinical use and has therefore attained the largest drug safety data base. Omeprazole has a remarkable safety profile with most adverse events in the range of that of placebo treatment [81–83]. Challenges had been hypergastrinemia (also seen with the other PPIs) with subsequent induction of carcinoids in rats chronically exposed to high toxicological doses [84], gastric bacterial overgrowth due to anacidity [85], impaired absorption of vitamin B_{12} and iron [86], induction of cytochrome P450 IA2 which both generates and detoxifies mutagens [87], [88]; suspected genotoxicity [89], and very rare events not conclusively related to omeprazole treatment (impaired vision and hearing, inflammatory and immunologic events like fever, vasculitis and colitis). All of these issues have been reviewed by experts and considered to be of either no relevance or even unrelated to omeprazole treatment [86], [90–96]. The aforementioned adverse events published as case reports seem to be extremely rare relative to the large number of treatment courses with omeprazole of well above 100 million. Some of these adverse effects, however, disappeared upon cessation of omeprazole therapy and reappeared upon rechallenge suggesting a causal relationship. These include cases of myopathy [97], neuromyositis [98], erythema nodosum [99], arthralgia [100], pityriasis rosea-like skin eruption [101], hemolytic anemia [102], interstitial nephritis [103], [104], CNS-symptoms [105], [106], and acute gout [107].

Pantoprazole [*102625-70-7*], 5-(difluoromethoxy)-2-[[(3,4-dimethoxy-2-pyridyl)methyl]-sulfinyl]benzimidazole (WHO), sodium salt $C_{16}H_{15}F_2N_3NaO_4S$, M_r 405.38, [27], [53], [56], [108–111]. Figure 3 shows the synthesis of the sodium salt, Figure 4 its chemical activation. Pantoprazole is available as enteric coated tablets containing 45.1 mg of the sodium salt sesquihydrate equivalent to 40 mg of the racemic mixture of the free anhydrous acid, and as a lyophylisate for i.v. infusion. The (+)- and (−)-enantiomers do not differ in their antisecretory potencies in animals. An oral 20 mg formulation for GERD/maintenance therapy has been approved recently.

Trade names: Pantozol (Byk Gulden) and others; various licensed products under different trade names (see [23]).

3.2. H_2-Receptor Antagonists

H_2-receptor antagonists (H_2-RAs) are structural analogues of histamine that – at least those in clinical use – competitively and surmountably

Figure 2. Congruence between animal data, human pharmacology data and clinical data with respect to equipotency and equiefficacy of two gastric proton pump inhibitors.A) Inhibition of gastric acid secretion in various animal models: Inhibitory doses, ID_{50} values (µmol/kg; 1 µmol = 0.35 mg of omeprazole or 0.38 mg of pantoprazole, free acid). HPD = Heidenhain pouch dog, FR = acute fistula rat, GSR = Ghosh-Schild rat, 2-DG = 2-deoxy-D-glucose. The routes of administration refer to test drugs, not secretagogues (impromidine, penta. = pentagastrin, bethan. = bethanechol). For further information, see [56].B) 24 h-pH-metry in healthy volunteers (time of intragastric pH > 4). All doses 40 mg orally, daily over 7 d Left pair of columns: Koop et al. [40]. Right pair of columns: Brunner et al. [44]. The comparison between the two studies shows that, although PPIs may vary in their efficacy depending on the random sample, omeprazole and pantoprazole proved equipotent when compared intraindividually.C) Healing rates in gastroesophageal reflux disease (GERD), duodenal ulcer (DU), and gastric ulcer (GU) in a comparison between daily oral doses of either 20 or 40 mg omeprazole or 40 mg pantoprazole. Selected studies that show a clear cut advantage of the 40 mg dose. From left to right: Hetzel et al. [45]; Laursen et al. [46]; Bate et al. [47]; Lauritsen et al. [48]; Walan et al. [49]; Valenzuela et al. [50]; Witzel et al. [51]. The specifications "all" and "> 1 cm" below the sixth group of columns [50] refer to the ulcers evaluated. p-Values are indicated at the bottom of columns compared to each other. All of the differences between the two doses shown in the figure are statistically significant irrespective of the particular drug involved. It is important to note that the failure of other studies (not shown here; see [50] and [53]) to demonstrate any significant difference between the healing rates upon 40 mg pantoprazole compared to 20 mg omeprazole does not conflict with the aforementioned superiority of the 40 mg dosage. In fact, 40 mg of either drug represent a ceiling dose separated by a comparatively small difference from the healing rate upon 20 mg. Thus, both of the two doses are localized in the upper portion of the dose response curve. Because of the large interindividual variation seen in clinical studies, the difference will be statistically significant in one, but statistically insignificant in another study.

block the H_2-receptors located on the basolateral membrane of the parietal cell. Histamine is the major secretagogue in humans [33], [112]. An imidazole ring as part of the structure was originally regarded essential for specific H_2-antagonism but this was refuted by the newer H_2-RAs (see [113]). They show a similarly favorable safety profile as the PPIs [114] but face the problem of about 10 % resistant peptic ulcers [115] and loss of effectiveness by about 50 % over a 4-week treatment course (tolerance development [116]). Potential reasons have been discussed in [117], [33]. Table 2 shows the chemical structures of the H_2-RAs. In contrast to cimetidine (imidazole ring), the newer compounds contain thiazole (famotidine and nizatidine), furan (ranitidine) or piperidine and benzene (roxatidine) ring systems. This helps to avoid unwanted cytochrome P450, i.e., metabolic drug interactions [118]. The individual drugs are discussed in the following in alphabetical order.

Table 2. Chemical structures of H_2-receptor antagonists. Note the different ring systems. The imidazole ring is mainly responsible for metabolic drug interactions [118].

Cimetidine

Famotidine

Nizatidine

Ranitidine

Roxatidine

Figure 3. Synthesis of pantoprazole sodium as an example of PPIs [108]

Cimetidine [*51481-61-9*], 1-cyano-2-methyl-3-[2-[[(5-methylimidazol-4-yl)methyl]-thio]ethyl]guanidine (WHO) [119], $C_{10}H_{16}N_6S$, M_r 252.34, *mp* 141 – 143 °C, solubility in water at 37 °C 1.14 wt % increased by dilute HCl, pK_a-values 6.8 and 7.1. Cimetidine is a crystalline powder with bitter taste and characteristic odor. Citmetidine was the first of the H_2-RAs and revolutionized peptic ulcer therapy when introduced in the 1970s [120].

Trade names: Tagamet (SmithKline Beecham) and numerous others (see [23]).

Figure 4. The chemical activation pathway of substituted benzimidazoles exemplified by pantoprazole (according to [27])E = enzyme

Famotidine [*76824-35-6*], [1-amino-3-[[[2-[(diaminomethylene)-amino]-4-thiazolyl]-methyl]thio]propylidene]-sulfamide (WHO) [121], $C_8H_{15}N_7O_2S_3$, M_r 337.43, *mp* 163 – 164 °C, solubility in water at 20 °C 0.1 wt %.

Trade names: Pepdul (Merck Sharp & Dohme) and numerous others (see [23]).

Nizatidine [*76963-41-2*], *N*-[2-[[[2-[(dimethylamino)methyl]4-thiazolyl]methyl]-thio]ethyl]*N'*-methyl-2-nitro-1,1-ethenediamine (WHO) [122], $C_{12}H_{21}N_5O_2S_2$, M_r 331.45, *mp* 130 – 132 °C, solubility in water 0.1 – 0.33 wt %, pK_a-values 2.1 and 6.8.

Trade names: Nizax (Lilly) and others (see [23]).

Ranitidine [*66357-35-5*], *N*-[2-[[5-[(dimethylamino)-methyl]furfuryl]thio]ethyl]*N'*-methyl-2-nitro-1,1-ethenediamine (WHO) [123], $C_{13}H_{22}N_4O_3S$, M_r 314.41, *mp* 69 – 70 °C, freely soluble in water. Ranitidine was the second H_2-receptor antagonist introduced in the early 1980s. It further optimized peptic ulcer therapy by minimizing unwanted interactions with androgen receptors and cytochrome P450 (see above). It has a higher affinity and, hence, greater potency compared to cimetidine which, however, is important only in the context of the relative drug safety margins.

Trade names: Zantic (Glaxo) and numerous others (see [23]). Ranitidine is also available as Raniditine bismuth citrate used in H.p.-positive ulcer patients (see Section 3.4.5).

Roxatidine [*78273-80-0*], *N*-[3-[(α-piperidino-*m*-tolyl)oxy]-propyl]glycolamide (WHO) [124], $C_{17}H_{26}N_2O_3$, M_r 306.41, *mp* 59 – 60 °C.

Trade name: Roxit (Albert-Roussel).

3.3. Antacids

Starting with naturally occurring carbonates centuries ago and later followed by potash combined with bismuth more than one century ago, antacids have since been developed and widely used over decades (see [125]). They are better than placebos and as effective as cimetidine in DU healing but less effective in GU healing [125]. Available both as liquids and tablets, they are nowadays usually taken 1 h after each meal and at bedtime in a total daily dose equivalent to about 400 mmol neutralizing capacity. This should be sufficient for all patients while minimizing adverse effects (see below). Such regimens elevate intragastric pH above 3.5 for about 2 h. Water-insoluble, aluminum – magnesium-containing antacids (like magaldrate) leave the stomach more slowly with the solid meal portion and are therefore longer acting. In addition to acid neutralization, these aluminum-containing antacids enhance the production of mucosal prostaglandins and possibly SH-containing compounds to protect the mucosa from injury ("gastroprotection") [125]. In therapy and prevention of mild GERD, acid neutralization, subsequent partial pepsin inactivation, and binding of bile acids and lysolecithin may act in concert (see [125]). Antacids display a favorable cost : benefit ratio in mild diseases.

More severe cases of acid related disorders require PPIs (see Section 3.1).

Although antacids did not display any teratogenic effects in animals and may therefore be used in pregnancy- and delivery-associated GERD (see [125]), they can interfere with iron absorption and may facilitate metabolic alcalosis and fluid overload. The latter effects depend on their bicarbonate and sodium ion content which is considered obsolete. In general, low sodium products should be preferred. Particulate antacids may also cause pneumonia upon aspiration and have been substituted for prevention of reflux complications largely by antisecretagogues. Nonulcer dyspepsia (NUD) and prophylaxis of NSAID-induced ulcers (see misoprostol, Section 3.4.1) are no recommended indications for antacids. Apart from the aforementioned adverse effects, aluminum-containing antacids can bind tetracyclines and many other drugs and thus prevent their absorption [21]. Aluminum-containing antacids may also complex phosphate (to cause osteomalacia in the worst case) and constipate the patient. The latter effect is counterbalanced by magnesium [21] contained in combination formulations such as magaldrate (see [126]), because magnesium salts in the intestine increase GI motility and cause osmotic diarrhea [127]. HCl converts insoluble aluminum oxide and hydroxide into more readily soluble and absorbable aluminum chloride. However, the causal relationship between aluminum intake with antacids and Alzheimer's disease is unlikely, while chronic intake of high doses may cause CNS toxicity in patients with renal insufficiency [128], [129].

Antacids containing carbonate, namely $NaHCO_3$ or $CaCO_3$, produce CO_2 with HCl and cause therefore gastric flatulence, belching and acid reflux. Na^+ may cause problems in hypertensive patients, Ca^{2+} adversely stimulates gastrin and HCl secretion ("acid rebound"). Those salts of carbonic acid are considered obsolete even in antacid mixtures although they are still used to some extent. Modern alternatives are the poorly soluble bases magnesium and aluminum hydroxide. If the two are incorporated together into one tridimensional lattice as represented by magaldrate (see below), they behave as a monosubstance buffering the pH between about 3 and 5 [130].

For tabulated overviews of antacids, see [21], [131], [132]. The indicated in vitro neutralization capacities do not necessarily reflect the relative therapeutic efficacies which are also affected by pH-dependent dissolution, viscosity, gastroprotective effects, etc. (see magaldrate). Antacid formulations may contain many additives such as simethicone (carminative contained in Riopan; see [131]); these are not considered here. Only the major antacid components which influence gastric acidity will be discussed below in alphabetical order.

Aluminum hydroxide [*21645-51-2*], $Al(OH)_3$, M_r 77.99, insoluble in water, soluble in dilute mineral acids and alkali hydroxides (4 % suspension in water), white, amorphous powder. For other relevant properties and production, see → Aluminum Oxide, Chap. 1.1. Available as $Al(OH)_3 \cdot nH_2O$ (algedrate) and algedrate hexitol complex. Depending on gastric acidity, stepwise buffering proceeds according to

$$Al(OH)_3 + 3\,HCl \rightleftharpoons Al(OH)_2Cl + H_2O + 2\,HCl$$
$$\rightleftharpoons Al(OH)Cl_2 + 2\,H_2O + HCl \rightleftharpoons AlCl_3 + 3\,H_2O$$

Pure $Al(OH)_3 \cdot nH_2O$ is not very stable, it ages at room temperature upon loss of water (formation of aluminum oxide) and neutralizing capacity. Aluminum hydroxide is preferably used as a combination preparation with magnesium hydroxide to counterbalance gut motility effects. This mixture also displays increased stability. Generated from aluminum hydroxide and gastric acid, aluminum chloride binds phosphate as insoluble $AlPO_4$ which is then excreted with feces. Aluminum hydroxide is therefore also used at mealtime in patients on dialysis to reduce phosphate intake. Magnesium containing antacids (see below) are contraindicated in this condition to avoid dangerous hypermagnesemia [132].

Trade names: Actal and numerous others (see [23]).

Aluminum phosphate [*7784-30-7*], $AlPO_4$, M_r 121.95, white powder, insoluble in water, soluble in concentrated mineral acids, pH 5.5 – 6.5 (4 % suspension in water). Available as $AlPO_4$ gel or $AlPO_4 \cdot 2\,H_2O$. For other relevant properties and production, see → Phosphoric Acid and Phosphates, Chap. 3.3.6.

Trade names: Phosphalugel (Boehringer Ingelheim) and others (see [23]).

Magnesium hydroxide [*1309-42-8*], $Mg(OH)_2$, M_r 58.32, amorphous powder, virtually insoluble in water (pH 9.5 – 10.5), soluble in dilute acids. For other relevant properties and production, see → Magnesium Compounds, Chap. 4. Available in combination preparations with aluminum hydroxide and under numerous trade names (see [23]). The equation for neutralization is

$$Mg(OH)_2 + 2\,HCl \rightleftharpoons MgCl_2 + 2\,H_2O$$

For potential side effects, see general discussion of antacids.

Magaldrate (hydroxymagnesium aluminate) [*74978-16-8*], $Al_5Mg_{10}(OH)_{31}(SO_4)_2 \cdot nH_2O$, insoluble in water, white, odorless crystalline powder, soluble in dilute mineral acids. Magaldrate [133] favorably combines the strongly basic properties of magnesium located in the crystal core with the less basic properties of aluminum ions surrounding the former in a layered lattice (Fig. 5). The magaldrate layered lattice consists of recurrent stacks of octahedral basic layers with an excess of positive charges $[Al_5Mg_{10}(OH)_{30}]^{5+}$ on the outer gel surface [134], [135]. These charges electrostatically interact with negative charges of the gastric mucus layer to favorably increase the antacid's retention time in the stomach [136].

Trade names: Riopan (Byk Gulden) and numerous others (see [23]).

In these brucite-like layers, about one third of the HO – Mg – OH units are substituted by positively charged $HO - Al^+ - OH$ units, counterbalanced by SO_4^{2-} and OH^- anions in the aqueous interlayer [137–139]. Compared to antacids composed of mixed hydroxides of aluminum and magnesium, magaldrate has a low aluminum content per milliliter and releases less aluminum because it rebinds aluminum ions in exchange for the more basic magnesium ions provided by an excess of antacid [140], [141]. A further advantage of the layered lattice is that its inner surface is not accessible to aluminum-binding proteins that otherwise reduce the buffering capacity of aluminum-containing conventional antacids [142]. In fact, although the in vitro acid-neutralizing capacity of magaldrate is similar to that of other antacids, its in vivo neutralizing capacity in humans is significantly higher [142] due to the exclusion of proteins [133]. However, magaldrate forms a gel with a large inner surface confining water spaces readily accessible to HCl. The alternation of magnesium and aluminum hydroxides within the layered lattice prevents losses of buffering capacity by aging. Magaldrate thereby shows prolonged acid neutralization up to the optimum of pH 4 [133]. In contrast, an aging phenomenon is found in aluminum hydroxide gels which is due to transition of aluminum hydroxide to aluminum oxide upon loss of water.

The magaldrate gel binds cholic acids like an anion exchanger, and it binds lysolecithin and pepsin on its outer surface [143]. It provides balanced, opposing actions of aluminum and magnesium on gut motility [21].

3.4. Miscellaneous Drugs

3.4.1. Prostaglandin Derivates
(→ Prostaglandins)

Prostaglandin (PG) derivatives exert gastroprotective effects at subantisecretory doses [144] but have the disadvantage of frequent side effects (mostly diarrhea and cramps) when administered at higher, antisecretory doses [128]. Only the latter accelerate healing of GU and DU. Prostaglandins seem to be somewhat inferior to H_2-receptor antagonists [145], particularly with respect to pain relief. Prostaglandins are abortifacient and are contraindicated during pregnancy and lactation. Low doses of PG derivatives have proved valuable in the prophylaxis of NSAID-induced peptic ulcers [21], [132]. Apart from the PG-E_1 derivative misoprostol (see below), other PG-E_1 (rioprostil) and PG-E_2 derivatives (arboprostil, enprostil, trimoprostil) had been under study [21], [146].

Misoprostol [*59122-46-2*], 15-deoxy-16-hydroxy-16-methyl-PG-E_1, (±)-Methyl-(1*R*,2*R*,3*R*)-3-hydroxy-2-[(*E*)-(4*RS*)-4-hydroxy-4-methyl-1-octenyl]-5-oxocyclopentaneheptanoate (WHO) [147], $C_{22}H_{38}O_5$, M_r 382.54, light yellow oil, slightly soluble in water. Misoprostol is approved for prophylaxis of

Figure 5. Schematic drawing of the layered lattice of magaldrate, a special example of an antacid (according to [134])

NSAID-induced ulcers and the treatment of DU and GU regardless of the limitations mentioned above.

Trade names: Cytotec (Heumann) and others (see [23]).

3.4.2. Prokinetic Drugs

Reflux esophagitis (GERD) is caused by reflux of gastric acid and therefore treated not only by PPIs and antacids but also by prokinetic drugs which facilitate oral to aboral clearing of the esophagus and emptying of the stomach [148]. Prokinetic drugs do so by alternately decreasing the frequency of intermittent lower esophageal sphincter relaxations, and increasing the amplitude and frequency of esophageal as well as gastric peristaltic contractions. Two pharmacological principles are used: (1) blockade of peripheral dopamine D_2-receptors by domperidone or metoclopramide which may lead to disinhibition of motility (although its mediation by D_2-receptor blockade is controversial), and (2) activation of peripheral 5-HT_4-receptors by either metoclopramide or cisapride. The latter interaction triggers the release of acetylcholine that subsequently stimulates motor neurons [149], [150]. Side effects relate primarily to either blockade of dopamine receptors (extrapyramidal motor and prolaktin effects as well as diarrhea; [151]) or release of acetylcholine (cramps, diarrhea; [152]). Domperidone has the advantage over metoclopramide of not significantly entering the central nervous system (CNS), thus avoiding central side effects. Although cisapride concentrations in rat brain can reach one-third to half of the plasma concentration, it does not block dopamine receptors and is therefore devoid of extrapyramidal motor and prolaktin effects [152]. Drug interactions by prokinetic drugs have been reviewed in [153].

Cisapride [*81098-60-4*], *cis*-4-amino-5-chloro-*N*-[1-[3-(*p*-fluorophenoxy)-propyl]-3-methoxy-4-piperidyl]-*o*-anisamide (WHO) [152], $C_{23}H_{29}ClFN_3O_4$, M_r 465.95, available as monohydrate, *mp* 109.8 °C is, like metoclopramide, a substituted benzamide.

Trade names: Propulsin (Janssen) and others (see [23]).

Domperidone [*57808-66-9*], 5-chloro-1-[1-[3-(2-oxo-1-benzimidazolinyl)propyl]-4-piperidyl]-2-benzimidazolinone (WHO) [154],

$C_{22}H_{24}ClN_5O_2$, M_r 425.92, *mp* 242.5 °C, available as maleate (M_r 544.06).

Trade names: Motilium (Byk Gulden) and others (see [23]).

Metoclopramide [*364-62-5*], 4-amino-5-chloro-*N*-[2-(diethylamino)-ethyl]-*o*-anisamide (WHO) [155], $C_{14}H_{22}ClN_3O_2$, M_r 299.81, *mp* 146.5 – 148 °C, solubility in water at 25 °C 0.02 wt %, pK_a-values 7.3 and 9.0. Metoclopramide is available as hydrochloride monohydrate (M_r 354.28) as a 10 % aqueous solution of pH 4.5 – 6.0.

Trade names: Gastrosil (Heumann) and many others (see [23]).

3.4.3. Antimuscarinic Drugs

The only antimuscarinic drug still used in peptic ulcer disease is pirenzepine which has limited selectivity for M_1-muscarinic receptors present on both intramural neurons and paracrine, histamine-releasing cells (i.e., ECL-cells) of the gastric mucosa [156], [157].

Pirenzepine [*28797-61-7*], 5,11-dihydro-11-[(4-methyl-1-piperazinyl)acetyl]-6*H*-pyrido[2,3-b][1,4]benzodiazepin-6-one (WHO) [158], $C_{19}H_{21}N_5O_2$, M_r 351.42, pK_a values 2.1 and 8.1. Pirenzepine is available as dihydrochloride monohydrate, M_r 442.36, soluble in water. Because of its unfavorable balance between weak antisecretory and frequent anticholinergic adverse effects (dry mouth, blurred vision), pirenzepine is considered obsolete [128].

Trade names: Gastrozepin (Thomae) and many others (see [23]).

3.4.4. Sucralfate

Sucralfate [*54182-58-0*], sucrose hydrogen sulfate basic aluminum salt (WHO), $C_{12}H_{54}Al_{16}O_{75}S_8$, M_r 2086.74, insoluble in water, soluble in dilute HCl or NaOH, pK_a 0.43 – 1.19.

Sucralfate was first introduced in Japan in the late 1960s. Numerous active components of sucralfate have been described which act in concert to make sucralfate a gastroprotective antiulcer drug [159], [160] that even displays "cytoprotective" actions (i.e., on a cellular level) in vitro [161]. Maintenance of mucosal blood flow ensures rapid repair of mucosal damage; increased mucosal bicarbonate and mucus secretion protects the mucosa; and binding of fibroblast growth factor and epidermal growth factor to the sucralfate gel adhering to the injured mucosa enhances angiogenesis and epithelization of ulcerated areas [160]. Stimulation of PG biosynthesis and release of somatostatin may contribute to these actions and may further explain reduction of both parietal cell responsiveness and ulcer relapse rate following ulcer healing by sucralfate [159]. These effects may also explain reduced acid secretion under sucralfate therapy [162]. In addition, sucralfate may interfere with the attachment of H.p. to the gastric epithelium and may thereby suppress to some extent (but not eradicate) H.p. infection [159], [162]. Healing rates with sucralfate are similar to, and ulcer relapse rates are even lower than those after, H_2-receptor antagonists [132],

[163]. Tolerability is excellent, with aluminum-induced constipation being the most prominent side effect seen in 2–4 % of the patients [132], [164].

Trade names: Ulcogant (Merck) and many others (see [23]).

3.4.5. Bismuth Compounds

A variety of bismuth compounds are available as antiulcer drugs.

Bismuth aluminate [*12284-76-3*], $Bi_2(Al_2O_4)_3$.

Trade name: Noemin (Trommsdorf) and others (see [23]).

Bismuth citrate is on the market as a colloidal ammonium–potassium salt which is a mixture of the corresponding salts of the bismuth citrate complex $[BiC_6H_4O_7]^-$ (K or $NH_4)^+$ (see below) and citric acid $[C_6H_5O_7]^{3-}$ 3(K or $NH_4)^+$. The so-called "colloidal bismuth subcitrate, CBS" in fact contains the aforementioned bismuth citrate complex [165] in which H^+ of one citric acid carboxyl group is substituted by either K^+ or NH_4^+. These units are further complexed to a colloidal material [166]. Bismuth citrate is highly soluble in water.

Trade names: Telen (Yamanouchi) and others (see [23]).

Bismuth subgallate [*99-26-3*], $C_7H_7BiO_7$, lipid solubility leads to a high rate of absorption, in contrast to the other salts (but see bismuth citrate).

Trade names: Bismofalk (Falk) and others (see [23]).

Bismuth subnitrate [*1304-85-4*], $BiO(NO_3)\cdot H_2O$.

Trade name: Angass (Medice).

Bismuth subsalicylate [*14882-18-9*], $C_7H_5BiO_4$.

Trade names: Jatrox (Procter & Gamble) and others (see [23]).

Mode of Action. These colloidal, basic bismuth preparations are, with the exception of bismuth citrate, almost insoluble in water. Depending on the actual pH, they form either colloidal solutions, highly hydrated gels, or thin films [167]. These cover the ulcerated areas, predominantly due to formation of bismuth oxychloride BiOCl, but also more complex structures containing free COOH and BiO^+ groups. These structures are precipitated from bismuth salts by gastric acid. Bismuth citrate is highly soluble in water but precipitates in an acid medium when the solubility product of its free acid (formed according to $R\text{–}CH_2CO_2^- + H^+ \rightleftharpoons R\text{–}CH_2CO_2H$) is exceeded [168]. Apart from the tenacious layer formed on the mucosa at low pH (see above), bismuth salts display a variety of additional action components that may be partially related to their reaction with thiol groups [169] and proteins [170], [171]. These additional effects include stimulation of PGE_2 biosynthesis and bicarbonate secretion, and either stimulation of mucus secretion or inhibition of its enzymatic degradation. Bismuth compounds also depress pepsin activity by either chief cell inhibition or pepsin complexation, and inhibit many enzymes of H.p., thus limiting mucus degradation. Bismuth salts bind and thereby inactivate bile acids at low pH, and accumulate epidermal growth factor in the ulcer area which may accelerate healing due to its trophic actions. Bismuth salts exert antimicrobial activity, also in H.p. infections [172]. The above pharmacodynamics of bismuth have been reviewed in [168], [173], with special reference to bismuth citrate, and in general in [132]. Substantial bismuth concentrations in the mucus or within the mucosa are observed for only a few hours following administration. Therefore, the low ulcer relapse rate with bismuth compounds may partially be due to trace amounts of bismuth systematically absorbed and, due to slow excretion, still available in the gastric tissue over up to 3 months. Nonetheless, safety of therapy with bismuth compounds seems to be excellent with only mild and infrequent side effects [174]. Probably due to its pK_a value in the order of 3

and, therefore, its comparatively fair ability to penetrate the stomach wall under acidic conditions as an uncharged molecule, bismuth citrate may produce higher (although transient) peak plasma concentrations of bismuth than some of the other bismuth salts which are unstable under these conditions. However, no major toxic effects have been reported [174].

Ranitidine bismuth citrate (RBC) [*128345-62-0*], $C_{19}H_{27}BiN_4O_{10}S$, M_r 712.48, is a novel salt of the base ranitidine and the monobasic acid bismuth citrate (note that a widely used nomenclature is subcitrate instead of citrate, see above and [165]). Ranitidine bismuth citrate forms a suspension in water but is soluble at low pH values to release its components. According to [175] RBC inactivates pepsin and H.p. more efficiently than an admixture of its components due to its better solubility. However, as discussed in page 13, bismuth citrate released at low pH will again precipitate as soon as the solubility product of its free acid is exceeded. Ranitidine bismuth citrate has been developed for combination therapy with antibiotics for eradication of H.p. Depending on the co-prescription, eradication ranged from 15 to 92 % in an intention-to-treat analysis [176]. It is claimed to combine the antisecretory action of ranitidine with the antimicrobial and gastroprotective actions of bismuth.

Trade name: Pylorid (GlaxoWellcome).

4. Prospect for Future Developments

4.1. Reversibly Binding Acid Pump Antagonists

In contrast to PPIs which bind covalently to the proton (acid) pump (see Section 3.1), acid pump antagonists (APAs) bind reversibly and compete with potassium on the luminal (extracytoplasmic) side of the H^+/K^+-ATPase to interrupt its catalytic cycle [20]. This reversible blockade not only regards the activated pumps already incorporated into the apical membrane, but also the resting pumps [177] still present in cytoplasmic vesicles. The latter are devoid of any proton gradient, they are unable to activate PPIs for this reason, and probably amount to about one-third of the total pumps in a parietal cell during meal stimulation [33], [177]. APAs will therefore result in a more rapid and complete inhibition of acid secretion than PPIs on a first administration. The duration of this inhibition by APAs corresponds to the drug's actual plasma concentration as opposed to a prolonged inhibition with covalently binding PPIs [178], [179]. APAs with different chemical structures have been synthesized (for example, imidazopyridines and acylquinolines; see [178]) but not one has reached the market so far. Although these weak nitrogen bases, like the PPIs, accumulate within the acidic space of the parietal cell, their selectivity for the acid pump is based on a specific fit between their chemical structure and that of the acid pump, being in line with a competitive mode of action.

Pumaprazole [*158364-59-1*], methyl 2-[[(2,3-dimethylimidazo[1,2-a]pyridin-8-yl)amino]methyl]-3-methylcarbanilate (WHO), $C_{19}H_{22}N_4O_2$. Pumaprazole has been abandoned in favor of a pharmacologically better follow up compound presently under development at Byk Gulden. The WHO decided to label the APAs by the stem syllable "-prazole" in order "to maintain the number of stems at a manageable level", irrespective of the completely different (i.e., reversible vs. covalent) modes of drug – target interactions by APAs and PPIs (WHO decision communicated on Nov. 30, 1995). Unfortunately, this pharmacologically misleading but legally binding decision will confuse the rational use and differential perception of APAs vs. PPIs in the future and counteracts the effort for an unambiguous terminology in pharmacology. It should be noted that the terms APAs and PPIs have been coined specifically to make a clearly recognizable distinction between the two chemically and mechanistically different classes of drugs.

4.2. Drugs Directed Against *Helicobacter pylori*

Helicobacter pylori (H.p.) has been recognized as a causal factor of most peptic ulcers (see Chap. 2). While companies worldwide try to develop antimicrobials both specific for H.p. and effective as a monotherapy, current therapy still takes advantage of the available reper-

toire of antibiotics [180–183] (→ Antibiotics). Although it has been claimed that antibiotics alone can eradicate H.p. infection and heal DU [184], present eradication regimes include one of the PPIs (see [180–183]) to enhance the effect of the antibiotics by a mode of interaction still under debate [185]. One-week triple therapies consisting of a PPI in combination with two of the three antibiotics amoxicillin (→ Antibiotics, Chap. 4.), clarithromycin, and metronidazole (→ Imidazole and Derivatives, Chap. 4.3.) are the therapies of choice according to the Maastricht consensus report [186].

5. Relative Drug Assessment

BURGET et al. [187] have published a model predicting the healing rates in DU, increasing up to an optimum defined by both a pH threshold and the percentage time the intragastric pH was above this threshold during a 24-h-period. A similar relationship in GERD treatment was later reviewed by HUNT [188]. It generally means that the longer the duration and the higher the degree of pH elevation by a certain drug is, the better the healing rate will be, up to an optimum which depends on the particular disease (GERD, GU, DU, Zollinger – Ellison Syndrome). This clearly favors the PPIs (see Section 3.1) for treatment of the H.p.-unrelated reflux esophagitis [189], [190]. The superiority of PPIs also shows in treatment of GU and DU with the limitation that any therapy eradicating H.p. (see Section 4.2) or suppressing H.p. in addition to gastroprotective effects (see Sections 3.4.4 and 3.4.5) seems to reduce the ulcer relapse rate compared to exclusively antisecretory drugs [191]. An interesting observation in this context is that eradication of H.p. may provoke GERD [192] or DU [193]. This may be due to the loss of neutralizing (NH_3) or antisecretory compounds that had been produced by H.p. in the patient's stomach before eradication therapy [194]. Obviously, this observation of DU induction by H.p. eradication therapy relates to the well known, low percentage of peptic ulcer cases causally independent of H.p. infection.

NSAID-induced peptic ulcers [195] can be prevented by prophylactic treatment with subantisecretory doses of misoprostol (see Section 3.4.1) but less so with H_2-receptor antagonists [196]. Of course, also PPIs are very effective prophylactic drugs [197]. Antacids have maintained their place in "common heartburn", gastritis, and less severe cases of GERD or GU and DU [132], although they constitute an inferior treatment option. Their major application will only be as cheap self-medication remedies.

1. Introduction

Parasitism is a special form of intimate relationship between two species. One species, the host, is to some degree injured through the activities of the other species, the parasite. The parasite need not be parasitic through all stages of its existence. Parasites living within the host are distinguished as endoparasites, e.g., helminths, from those found on the surface of the body, the ectoparasites, e.g., arthropods. There are forms of close biologic relationships other than parasitism. Commensalism denotes an association beneficial to one partner and at least not disadvantageous to the other. Mutualism (or symbiosis) denotes an association that is mutually beneficial.

This article describes only the helminth infections of humans. Infections caused by other parasitic organisms, such as protozoa and ectoparasites, are described elsewhere (→ Chemotherapeutics, → Dermatotherapeutic Agents), as are the veterinary parasitoses (→ Veterinary Drugs).

This article is not intended to be a guide to therapy, and mention of a drug is not to be taken as an endorsement. Chapter 2 describes the helminth parasites of humans and the diseases they cause, and Chapter 3 describes the drugs that may be used to control the parasites.

2. Parasitic Worms

Helminths are the wormlike organisms classified in two phyla, the flatworms (Platyhelminthes), comprising the flukes (or trematodes) and the tapeworms (or cestodes), and the roundworms (Nemathelminthes). The roundworms are also called nematodes. Therefore, "helminth" refers to three morphologically different groups: flukes, tapeworms, and roundworms. Most flatworms are hermaphroditic, having both male and female reproductive organs within the same individual, and are parasites. In contrast, the roundworms have separate sexes and are overwhelmingly free living. Nevertheless, a number of roundworm species are parasitic, affecting humans, animals, and plants.

2.1. Trematodes (Flukes)

2.1.1. Blood Flukes (*Schistosoma* spp.)

Three species of schistosomes cause most human schistosomiasis infections: *Schistosoma mansoni* and *S. japonicum* (locally also *S. intercalatum* and *S. mekongi*) cause the intestinal form of the disease, whereas *S. haematobium* (rarely *S. mattheii*) causes the urinary form.

Distribution. *S. haematobium:* all over Africa, in the Near East (Syria to Iran and Yemen), islands off East Africa. *S. mansoni:* throughout most of Africa southeast of a line from Gambia to Libya, Arabian peninsula, Brazil, Venezuela, Surinam, some Antilles Islands. *S. japonicum:* southern half of continental China, the Philippines; however, virtually extinct in Japan. *S. mekongi:* Laos, Cambodia. *S. intercalatum:* Cameroun to the Congo Basin. *S. mattheii:* restricted to southern Africa. About 270 million people are infected [13]. Annually, about one million deaths are caused by schistosomiasis [14].

Development. The schistosomes differ in many aspects from all other human flukes. They are elongate, wormlike, and live within the blood vessels. They have separate sexes. The adult parasites *S. mansoni* and *S. japonicum* are found as pairs in the mesenteric veins, whereas *S. haematobium* inhabits the veins of the vesical plexus. Adult males are 10 – 15 mm long and 0.5 – 1 mm wide. Their lateral body seams are folded downwards, forming a tube, the gynecophoric canal, which holds the female, which can be up to 28 mm long. The females deposit eggs, a few dozen to several thousand per day, depending on the species. About three fourths of the eggs laid are retained in the tissues of the body – mainly the liver and the intestinal and bladder walls – where they die within three weeks. The other eggs pass through the tissues into the lumen of the intestine or the bladder. They contain a larva, the miracidium, which hatches as soon as the eggs are voided into fresh water. The miracidium swims through the water in search of an appropriate snail (its intermediate host), penetrates the snail's tissues, and begins to multiply. After 4 – 7 weeks another type of larva, the cercaria, is released from the snail. These cercariae locate human skin exposed to water and penetrate it. Within another 6 – 12 weeks the juvenile schistosomes migrate through the vascular system and lungs to their predilected sites, mature, pair, and start laying eggs. The normal lifespan of schistosomes is 2 – 7 years. However, some parasites can survive and produce eggs for as long as thirty years.

Clinical Features. Severe itching (cercarial dermatitis) may occur at the site of skin penetration, and fever may occur during the migration phase of the parasite. In established infections, the egg incites an inflammatory reaction around the site where it is deposited in the tissues. This leads to fibrosis and calcification of the bladder, hematuria, uretric and renal involvement, and bladder cancer (*S. haematobium*). In the intestinal form of the disease (*S. mansoni* and *S. japonicum*) symptoms encountered are diarrhea, weakness, abdominal pain, splenomegaly, hepatic and portal fibrosis, portal hypertension, ascites, and carcinoma of the colon. Severe infections with *S. japonicum* can interfere with normal growth and mental development.

Therapy: praziquantel, oxamniquine, metrifonate, niridazole, hycanthone.

2.1.2. Lung Flukes (*Paragonimus* spp.)

Distribution. *P. westermani:* East Asia (Korea, Japan, China, Philippines, Indonesia). *P. kellicotti:* North America. *P. africanus:* Gabon to Zaire; several other species ranging from Mexico to Peru. About 20 million people are infected [15].

Development. The adult parasites measure 8 – 16 mm by 4 – 6 mm. They are found in pulmonary cysts that are formed by destroyed tissue and that connect to the respiratory passages of the lung. Eggs are voided with the sputum or the feces. Once eggs reach fresh water, a larva, the miracidium, develops within 2 – 4 weeks. The miracidium hatches from the egg, actively penetrates into specific aquatic snails, and multiplies. After 8 – 10 weeks, cercariae begin to be released from the snail. They locate crabs or crayfish, penetrate them, and encyst in the musculature as metacercariae. The crustaceans can also

become infected by feeding on infected snails. Humans acquire the infection by ingesting raw or improperly cooked crab meat or juice. The juvenile flukes excyst in the small intestine, penetrate the gut wall, and migrate through the diaphragm into the pleural cavity, where they penetrate the serosal layers of the lungs. Finally they arrive in the vicinity of the bronchioles. Within six weeks they develop into adult worms in tissue capsules that rupture and thus connect with the air ducts. These parasites can live for up to twenty years. Many mammals can act as carriers for human lung flukes. However, their importance as reservoir hosts is largely unknown.

Clinical Features. Mild infections: fever and cough. Severe infections: dry cough, violent blood spitting, weight loss, fever, pleural effusion, chest pain.

Therapy: praziquantel, bithionol.

2.1.3. Liver Flukes

Infections are caused by *Clonorchis sinensis, Opisthorchis viverrini*, or *O. felineus.* Infections with the cosmopolitan liver flukes of ruminants (*Fasciola hepatica, Dicrocoelium dendriticum*) may be important locally.

Distribution. *C. sinensis:* Korea, China, Southeast Asia, Japan, Taiwan, Philippines, Indonesia. *O. viverrini:* Laos, Thailand, Indian subcontinent. *O. felineus:* USSR and some European foci. About 50 million people are infected [15].

Development. Adult *C. sinensis* and *O. viverrini* (10 – 20 and 8 – 12 mm long, respectively) live in the intrahepatic bile ducts. Their eggs contain fully developed larvae, the miracidia, which are voided with the feces and ingested by aquatic snails. The parasitic larva (miracidium) hatches in the intestine of the snail, enters its tissues, and starts multiplying. After some time cercariae are released into the water. They infect cyprinid fish percutaneously, encyst in the fish musculature, and become infective metacercariae in about four weeks. Infection is acquired through the consumption of raw or improperly cooked fish. The young flukes excyst in the small intestine, migrate into the bile ducts, and mature within four weeks. They may then live for several decades. Dogs, cats, and pigs are important reservoir hosts.

Clinical Features. Mild infections: generally asymptomatic. Severe infections: dilation and fibrosis of the bile ducts, hemorrhage, digestive disturbances. Chronic infections: epigastric pain, anorexia, cholangitis, liver necrosis, bile duct and pancreas carcinoma, intrahepatic calculi.

Therapy: praziquantel, bithionol.

2.1.4. Giant Intestinal Fluke (*Fasciolopsis buski*)

Distribution. South China, Southeast Asia, Indonesia, and the Indian subcontinent. Two to ten million people are infected [15].

Development. The eggs of the giant intestinal fluke are voided with the feces. In fresh water a miracidium develops in 3 – 7 weeks, hatches, locates an aquatic snail, penetrates it, and begins multiplying. After 4 – 8 weeks cercariae begin to be released, and they encyst as metacercariae on aquatic plants. Infection is acquired when such plants (water caltrop, *Trapa* spp.; water chestnut, *Eleocharis* sp.) are peeled with the teeth. The metacercarial cysts are thus freed, are swallowed, and develop to sexually mature flukes (5 – 7 cm long) in the small intestine within about three months. Pigs, dogs, and rabbits are important reservoir hosts.

Clinical features. Mild infections are often asymptomatic. In severe infections there are generalized toxic and allergic symptoms, diarrhea, weakness, malabsorption, edema, ascites, abdominal pain, and gastrointestinal hemorrhage.

Therapy: praziquantel, niclosamide.

2.1.5. Lesser Intestinal Flukes

Several species of these small flukes (2 – 7 mm in length) are found in humans: *Echinostoma ilocanum, E. lindoense, Heterophyes heterophyes,*

Metagonimus yokogawai, Gastrodiscoides hominis, Watsonius watsoni.

Distribution. East and South Asia, West Africa, Mediterranean countries, especially Egypt (*Heterophyes*). About 16 million people are infected [13].

Development. These parasites live in the small intestine. They have typical trematode life cycles, with a single intermediate host (*Gastrodiscoides* and *Watsonius*; metacercariae on aquatic plants) or two intermediate hosts. The second host can be fish (*Heterophyes* and *Metagonimus*) or snails and mussels (*Echinostoma*). Infection is acquired through the consumption of raw or improperly cooked plants, fish, or mollusks. The lesser intestinal flukes live and produce eggs for several months.

Clinical Features. Mild infections are often asymptomatic or show only nonspecific symptoms: diarrhea, abdominal discomfort, and headache.

Therapy: praziquantel, thiabendazole, niclosamide, bephenium.

2.2. Cestodes (Tapeworms)

2.2.1. Broad or Fish Tapeworm (*Diphyllobothrium latum*)

Distribution. Northern temperate zone (Finland, USSR, Alaska, Canada; small foci in northern Italy, Switzerland, and Chile). *D. pacificum:* coastal regions of Peru. There are several related species that infect humans (e.g., *Diplogonoporus* in Japan). About 2 – 9 million people are infected [6].

Development. *D. latum* is a typical ribbonlike tapeworm of extreme length (up to 10 – 15 m) living in the small intestine. After the eggs are voided with the feces into fresh water, a larva, the coracidium, is released. Larvae are ingested by small copepod crustaceans. When these are ingested by cyprinid fish, the parasites penetrate into the musculature of the fish and develop into the infective stage, the plerocercoid. Humans acquire the infection by consuming raw or improperly cooked fish.

Clinical Features. Infections are generally asymptomatic. When they do appear, symptoms include abdominal discomfort, dizziness, and fatigue. About 4 % of those infected develop clinical symptoms of a vitamin B_{12} deficiency indistinguishable from pernicious anemia.

Therapy: praziquantel, niclosamide.

Several related species that cannot develop to maturity in humans, but do so in other mammals, may infect humans accidentally. They can proliferate and cause painful inflammatory tissue reactions. This rare condition, sparganosis, can be treated only by surgical removal. Praziquantel may prove to be effective.

2.2.2. Beef Tapeworm (*Taenia saginata* = *Taeniarhynchus saginatus*)

Distribution. Cosmopolitan, about 77 million people are infected [13].

Development. Adult beef tapeworms generally measure 3 – 10 m. Each day about ten proglottids of the ribbonlike body, the strobila, are shed, containing several hundred thousand eggs. When these eggs are ingested by cattle, a larva, the oncosphere, hatches from the egg and reaches the musculature (presumably by the circulatory system), where an infective larva, the cysticercus, develops within 10 – 12 weeks. Cattle may carry infective cysticerci in their muscles up to three years. Humans acquire the infection by consuming raw or improperly cooked beef. Within 3 – 4 months the parasite reaches maturity in the intestine. It may live up to twenty years.

Clinical Features. Infections often go unnoticed. In symptomatic cases: vague abdominal pain, nausea, weakness, loss of weight, increased or decreased appetite, headache.

Therapy: niclosamide, praziquantel, mebendazole.

2.2.3. Pork Tapeworm (*Taenia solium*)

Distribution. Almost cosmopolitan, wherever people eat improperly cooked pork. About 3 – 5 million people are infected with adult *T. solium* [15].

Development, clinical features, and therapy are all similar to those of the beef tapeworm.

Cysticercosis. Although pigs usually are the intermediate hosts in the life cycle of the pork tapeworm, humans can also become infected with the larvae of this parasite by ingesting the eggs, which remain viable in the soil for many weeks. The resulting infection, *cysticercosis,* occurs in Central and South America, South and East Asia, East Africa, and eastern Europe and may afflict more people than are infected with the adult tapeworm [15]. This condition is often accompanied by myositis and high fever. When the brain is involved (neurocysticercosis, developing in 1 – 5 % of the infected persons), this condition is often accompanied by epileptic attacks, meningoencephalitis, and intracranial hypertension. In South America alone, there are about 350000 cases [16].

Formerly, the only *treatment* for cysticercosis was surgical removal of larval cysts.

Therapy: praziquantel, niclosamide, mebendazole.

2.2.4. Dwarf Tapeworm (*Hymenolepis nana*)

Distribution. Cosmopolitan, about 45 – 50 million people, mainly children, are infected [15].

Development. The dwarf tapeworm is unique in that the adult can develop following ingestion of the eggs by humans. The larva, the oncosphere, that hatches from the egg develops to the cysticercoid stage in the intestinal mucosa within 4 – 7 days. Alternatively, infections may be acquired through accidental ingestion of grain beetles containing infective cysticercoid larvae. The adult tapeworm, developing from the cysticercoid to maturity in 1 – 2 weeks, grows up to 40 cm long.

Clinical Features. Mild infections are asymptomatic. Severe infections: abdominal pain, diarrhea, headache, dizziness, anorexia.

Therapy: praziquantel, niclosamide.

2.2.5. Dog Tapeworm (*Echinococcus granulosus, E. multilocularis*)

Distribution. *E. granulosus:* cosmopolitan, especially in sheep-rearing countries. *E. multilocularis:* small foci in North, Central, South, and East Europe, northern United States. About 100000 people are infected [15].

Development. Many mammals (*humans,* sheep, goats, cattle, pigs, dromedaries, horses, rodents) serve as intermediate hosts of these small (3 – 5 mm long) tapeworms that live as adults in the intestine of dogs or other canines. When humans ingest the eggs, larvae hatch, penetrate the gut wall, and generally lodge in the liver or lungs, although all other tissues can also be affected. The larvae grow extremely quickly, forming unilocular (*E. granulosus*) or multilocular (*E. multilocularis*) cysts. The cysts contain many protoscolices, which mature to adult worms when offal containing cystic material is fed to dogs.

Clinical Features. Cysts are often asymptomatic until they grow large, but then the symptoms become progressively severe. Symptoms depend on the location of the cysts. Liver cysts can cause symptoms resembling a mucoid carcinoma. Lung cysts give rise to coughing and chest pain, whereas cerebral cysts can cause serious neurological damage.

Therapy: surgical removal, in inoperable cases, mebendazole, which does not kill the parasite but arrests the progressive course of the disease.

2.3. Nematodes (Roundworms)

The parasitic nematodes are conveniently divided into two groups: the intestinal nematodes, including the roundworm, hookworm, pinworm, whipworm, threadworm, and trichina, and the

extra-intestinal nematodes, including the guinea worm and several species of filariae. The second group live in the tissues of fluids of the body and require an arthropod vector for the completion of their life cycles.

2.3.1. Roundworm (*Ascaris lumbricoides*)

Distribution. Cosmopolitan, common in humid tropical climates. About 1300 million people are infected [13].

Development. This large parasite (20 – 40 cm long) lives in the small intestine and feeds on gut contents. Each female produces over 200000 eggs per day. The eggs are passed with the feces, become infective in about one month, and can remain infective in the soil for up to fifteen years. After infective eggs have been ingested, e.g., with vegetables, larvae are released, penetrate the duodenal wall, and migrate through the liver and the blood vessels to the lungs. There they break through the alveolae into the air passages, ascend the trachea, are swallowed, and attain maturity in the gut about 8 – 10 weeks later. The females live about one year.

Clinical Features. The majority of infections are light and asymptomatic. Larvae in the lungs may cause pneumonitis (cough, wheezing, dyspnea). Complications are intestinal obstruction and worm irritation after medication, causing hepatic duct obstruction, appendicitis, and intestinal perforation.

Therapy: levamisole, pyrantel, piperazine, mebendazole, thiabendazole, albendazole. Ivermectin is in clinical development

2.3.2. Hookworms

Two species, *Ancylostoma duodenale* (common or Old World hookworm) and *Necator americanus* (American or New World hookworm), parasitize humans, causing one of the most important tropical diseases.

Distribution. *N. americanus:* the Americas, tropical Africa, South and East Asia. *A. duodenale:* from the Mediterranean through India to China and Southeast Asia, Brazil. *A. ceylanicum* is of local importance. About 930 million people are infected and about 60000 deaths are caused by hookworm infections each year [13], [14].

Development. The mature worms ($\approx$ 10 mm long) attach to the gut mucosa and suck blood (*Necator* 5 – 10 times less than *Ancylostoma*). Each female produces 10000 (*Necator*) or 20000 (*Ancylostoma*) eggs per day. These are voided with the feces and release larvae that develop in the soil within seven days to the infective stage, which is able to survive up to one month. Infection is percutaneous (*Ancylostoma* also oral). The larvae migrate to the heart and lungs. Subsequent development is as described for the roundworm (*Ascaris*).

Clinical Features. Mild, cutaneous reaction to the infective larvae and lung reactions (cough, wheezing) to the migratory larvae. Chronic phase: epigastric pain, tenderness, peptic symptoms, iron-deficiency anemia, protein-loss enteropathy, hypoproteinemia. Severe infections: high-output cardiac-failure dyspnea, edema. The symptoms of hookworm infections are often aggravated by malnutrition and secondary bacterial or other parasitic infections.

Therapy: pyrantel, thiabendazole, mebendazole, bephenium, levamisole, tetrachloroethylene, bitoscanate.

2.3.3. Pinworm (*Enterobius vermicularis*)

Distribution. Cosmopolitan, common in the developed countries of the northern hemisphere. About 350 million people are infected [13].

Development. The pinworm, which is more commensal than parasitic, lives in the lumen of the colon and feeds on gut contents. Gravid females migrate out of the anus to deposit their eggs (5000 – 10000), which are fully embryonated and infective within a few hours. Infections and reinfections are acquired through accidental oral intake of eggs. Larval development occurs in the intestine within about six weeks.

Clinical features. Perianal itching. Complications caused by ectopic migration are rare.

Therapy: pyrantel, piperazine, mebendazole, pyrvinium.

2.3.4. Whipworm (*Trichuris trichiura*)

Distribution. Cosmopolitan, especially common in warm and humid climates. About 690 million people are infected [13].

Development. The parasites (3 – 5 mm long) live attached to the cecal mucosa. The eggs are voided with the feces and require a period of at least three weeks to become infective. Eggs remain infective in the soil for over one year. The larvae hatch after eggs have been ingested, e.g., with vegetables or dirt, and mature in the intestine within 2 – 3 months. The adults live 3 – 10 years.

Clinical Features. Infections are generally asymptomatic; occasionally, abdominal discomfort and, in children, diarrhea occur.

Therapy: oxantel, mebendazole, thiabendazole, albendazole. Ivermectin is in clinical development.

2.3.5. Threadworm (*Strongyloides stercoralis*)

Distribution. Tropical and subtropical climates, extending into southern Europe and southern United States. About 80 million people are infected [15].

Development. The female worms live attached to the mucosa of the small intestine, on which they feed. They produce, usually parthogenetically, larvae that are infective shortly after passage of the feces and infect humans percutaneously. Their further development to maturity takes about 17 days and resembles that of hookworms. Autoinfection is possible when larvae mature in the gut and infections may be perpetuated up to twenty years. When environmental conditions are favorable, threadworms can exist for some time as free-living nematodes, completing several generations in the soil.

Clinical Features. Infections may be asymptomatic, but gastrointestinal symptoms (diarrhea, katarrhal enteritis, central epigastric pain) are common. In cases of severe infection the prognosis is poor, and the mortality rate is high.

Therapy: thiabendazole, mebendazole, albendazole. Ivermectin is in clinical development.

Infections with other nematodes (e.g., *Angiostrongylus, Anisakis, Capillaria, Dipetalonema, Gnathostoma, Oesophagostomum, Trichostrongylus*) are less important and generally respond to thiabendazole and/or mebendazole. Thiabendazole is also effective against migrating larvae of nematodes that normally mature in other mammals (cutaneous and visceral larva migrans). About 5 – 10 million people are infected [15].

2.3.6. Trichina (*Trichinella spiralis*)

Distribution. Cosmopolitan except Australia. About 46 million people are infected [13].

Development. Infection is initiated by the consumption of raw or improperly cooked meat (especially pork) containing the encysted larvae. These excyst in the gut and mature to adult worms in the gut wall within 3 – 4 days. Sexes mate in the gut lumen, and each female then produces up to 2000 larvae within two weeks. The larvae penetrate the gut wall, enter the lymphatic vessels, disseminate via the circulatory system throughout the body, develop in the muscle, and finally encyst in muscle fibers.

Clinical Features. Infections are generally asymptomatic during the intestinal phase. The muscle infection causes myositis, eosinophilia, leukocytosis, and occasional fever.

Therapy: thiabendazole, mebendazole, albendazole. Ivermectin is in clinical development.

2.3.7. Larvae of Toxocara canis, Toxocara cati, Ancylostoma brasiliense and Ancylostoma caninum

Distribution. Cosmopolitan.

Development. Humans, especially children are the "wrong hosts" for these larvae. Human infection are rare and occur through oral ingestion of larvae following contact with contaminated faeces of *Toxocara canis* infected dogs or *T. cati* infected cats or with contaminated soil, sand, or playgrounds. The larvae of *Ancylostoma brasiliense* or *Ancylostoma caninum* penetrate the skin ("creeping eruption") following contact with contaminated dog or cat faeces.

Clinical Features. The disease is determined by the site where larvae reside. Larvae migrantes viscerales of *T. canis* and *cati* are mostly observed in liver and lungs, occasionally in eyes or brain. Larvae of *Ancylostoma brasiliense* are called larvae migrantes cutaneae, larvae of *Ancylostoma caninum* are called epidermis larvae.

Therapy: Thiabendazole, diethylcarbamazine.

2.3.8. Guinea Worm (*Dracunculus medinensis*)

Distribution. Focally in West, North, and East Africa, the Middle East, from Iran through Pakistan into Indonesia. About 50 – 100 million people are infected [15].

Development. The parasites develop in the body cavity and deeper connective tissue for about 12 – 14 months. The mature females then migrate to the subcutaneous tissues, mainly of the legs. There they cause blisters and ulceration, through which large numbers of larvae are discharged when the skin contacts water. If taken up by copepod crustaceans, the larvae develop in the body cavity and become infective in 2 – 3 weeks. Humans acquire the infection by drinking water containing infected copepods. Dogs are known reservoir hosts.

Clinical Features. Infections are usually asymptomatic for one year. Specific signs of the disease are painful blisters and ulcerations of the skin where the females penetrate the skin. Secondary bacterial infections often cause additional complications.

Therapy: Careful mechanical extraction, thiabendazole. Both niridazole and metronidazole reduce the inflammatory tissue reactions without affecting the parasites.

2.3.9. Lymphatic Filariae (*Wuchereria bancrofti, Brugia malayi*)

Distribution. *Wuchereria:* throughout the tropics and subtropics. *Brugia malayi:* from India to Korea and Indonesia. *B. timori:* Timor. About 380 million people are infected [13].

Development. The adult parasites, the macrofilariae, live in lymphatic ducts and nodes. The females deposit eggs, from which larvae, the microfilariae, hatch. The larvae are distributed with the blood throughout the body but congregate in the peripheral vasculature during the night. From there they are taken up by mosquitoes and mature to infective larvae in their musculature. They then enter the proboscis of the mosquito, and when it takes another blood meal they enter the human skin through the puncture. In the new host, they mature and mate, and the females start producing the next generation of microfilariae.

Clinical Features. Infections generally are asymptomatic, but chronic lesions, presumably of an allergic nature, can cause lymphangitis and obstruction of lymphatic drainage, leading to elephantiasis and hydrocele.

Therapy: diethylcarbamazine.

2.3.10. Convoluted Filaria (*Onchocerca volvulus*)

Distribution. Africa south of the Sahara, Yemen, Mexico to Venezuela. About 40 million people are infected [14].

Development. The adult worms (macrofilariae) live in subcutaneous nodules. The larvae (microfilariae) collect in the superficial layers of the skin and are transmitted by black flies (*Simulium*), in which they develop to the infective stage. Humans are infected when the fly takes another blood meal.

Clinical Features. Microfilariae may cause chronic cutaneous lesions. Invasion of the eye: conjunctivitis, keratitis, iridocyclitis, chorioretinitis, glaucoma, opacity of the lens, leading to optic atrophy and blindness.

Therapy: diethylcarbamazine (microfilaricidal), suramin (macrofilaricidal), ivermectin (microfilacricidal).

2.3.11. African Eye Worm (*Loa loa*)

Distribution. Rain forests of West and Central Africa. More than 10 million people are infected [15].

Development. The adult parasites (macrofilariae) actively migrate through the subcutaneous tissue. The microfilariae are found in the peripheral blood during the day and are transmitted by flies (*Chrysops*).

Clinical Features. Allergic swelling of the skin.

Therapy: diethylcarbamazine.

3. Anthelmintic Drugs

The anthelmintic drugs are listed alphabetically. The *mechanism of action* of the older anthelmintics can be found in [17]. The numerous *trade names* for the older drugs are given for some twenty countries in [18]. A number of trade names are given in [19]. The national drug directories can also be consulted.

Albendazole [*54965–21–8*], methyl-(5-(propylthio)-2-benzimidazol)carbamate, $C_{12}H_{15}N_3O_2S$, M_r 265.3, *mp* 208 – 210 °C, is a colorless crystalline solid. It is insoluble in water, sparingly soluble in dimethylformamide or dimethylsulfoxide, and soluble in formic acid.

The compound is synthesized in a five step synthesis. 4-chloro-2-nitroaniline is first acetylated with acetic anhydride to give 1-acetamido-4-chloro-2-nitrobenzene. Treatment of this intermediate compound with potassium thiocyanate furnishes the key intermediate 1-acetamido-2-nitro-4-thiocyanatobenzene. Conversion of the thiocyanato group into the required *n*-propylthio analogue, with a simultaneous conversion of the acetamido group to the free amine, is effected by treating the last intermediate with 1-bromopropane in the presence of a base. Further reduction of the nitro group provides the diamine, which is subsequently ring closed to albendazole [20].

Albendazole is used against nematode infections: *Ascaris*, *Necator, Ancylostoma*, *Trichuris, Enterobius*, and systemic nematodes such as *Trichinella spiralis*, *Gnathostoma spinigerum*, and larval *Angiostrongylus cantonensis*. In addition it is used against the larval stages of the cestodes *Echinococcus granulosus* and *E. multilocularis* and for treatment of neurocysticercosis caused by *Taenia solium* [21].

Occasional *adverse effects* include fever, reversible leucopenia, headache, nausea, dizziness, sleeplessness, epigastric pain and diarrhoea. When higher dosages are given over a long period elevated levels of transaminases are observed, seldom hepatitis and occasionally alopecia. Contraindications are pregnancy and liver cirrhosis. Albendazole interferes selectively with the polymerization of β-tubulin to microtubuli. The microtubules play a crucial role in several important cell functions such as material transport within cells and neurotransmission [22].

Trade names: Eskadole (Smith Kline Beecham), Valbazen (Pfizer).

Bephenium [*3818-50-6*], benzyldimethyl-(2-phenoxyethyl)ammonium 3-hydroxy-2-naphthoate, $C_{28}H_{29}NO_4$, M_r 443.5, *mp* 170 – 171 °C, is a bitter tasting, odorless, yellow crystalline solid. It is insoluble in water and slightly soluble in ethanol.

The compound is synthesized by the reaction of dimethyl(2-phenoxyethyl)amine with benzyl halide [23].

Bephenium can be used against *Ascaris, Ancylostoma*, and *Trichostrongylus* infections; it is less effective against *Necator.* Occasional adverse reactions occur: nausea, diarrhea, vomiting, headache, vertigo.

Trade names: Alcopar(a) (Wellcome, Tanabe); Befen (Andromaco); Lecibis (Andromaco, Columbia); Debephenium (ICN Usafarma); Fedal Uncin (Hosbon-Fedal); Hebe (Farmacon); Befeval (Valmorca); Befenium (Laquifa).

Bithionol [*97-18-7*], 2,2′-thiobis(4,6-dichlorophenol), $C_{12}H_6Cl_4O_2S$, M_r 356.1, *mp* 188 °C, is a tasteless, colorless, crystalline solid. It is insoluble in water but soluble in ethanol.

Bithionol is synthesized by the reaction of chlorophenol with sulfur dichloride and sulfuryl chloride [24].

Bithionol can be used against liver, lung, and intestinal flukes. Frequent adverse reactions are abdominal pain, diarrhea, anorexia, nausea, vomiting, dizziness, headache, skin rashes, urticaria. Hepatic and renal involvement are rare complications.

Trade names: Actamer (Monsanto); Bitin (Tanabe); Bitin S (Tanabe), which contains the sulfoxide of bithionol.

Diethylcarbamazine [*1642-54-2*], *N,N*-diethyl-4-methyl-1-piperazinecarboxamide citrate, $C_{16}H_{29}N_3O_8$, M_r 391.4, *mp*141 – 143 °C, is a white, odorless, crystalline solid with a bitter acid taste. It is freely soluble in water or hot ethanol but insoluble in acetone, chloroform, ether, or dioxane.

The compound is synthesized by the reaction of diethylcarbamoyl chloride with methylpiperazine [25].

Diethylcarbamazine dihydrogen citrate is used against the microfilarial stage of filariae. It also kills the adult filariae of *Wuchereria, Brugia,* and *Loa.* Occasional adverse reactions are anorexia, nausea, vomiting, headache, and drowsiness. Allergic reactions occur, especially in onchocercosis patients: intense pruritus, edema, lymphadenitis, dermatitis, papular rash, fever, tachycardia.

The most likely mechanism of action is a rapid effect on the surface of the microfilariae. Previously hidden antigenic determinants become accessible to the immune system of the host, which then eliminates the microfilariae from the circulating blood [8].

Trade names: Hetrazan and Hetrazan 1949 (Lederle); Banocide (Wellcome); Notezine (Specia); Supatonin (Tanabe); Carbilazine (Willows Francis); Caricide (Am. Cyanamid).

Ivermectin (synonyms: 5-*O*-Demethyl-22,23-dihydroavermectin A_{1a}, 22,23-Dihydroabamectin, 22,23-Dihydroavermectin B_1) *Ivermectin* B_{1a} [*71827–03–7*], $C_{48}H_{74}O_{15}$, M_r 891.1, *mp* 155 – 157 °C; ivermectin B_{1b} [*70209–81–3*], $C_{47}H_{72}O_{15}$, M_r 877.1, is a white powder and forms crystals from ethanol – water. It is soluble in methyl ethyl ketone, propylene glycol, and poly(ethylene glycol).

Ivermectin

Ivermectin is a mixture of at least 80 % ivermectin B_{1a} (R = CH_3) and not more than 20 % ivermectin B_{1b} (R = H).

Ivermectin is a semisynthetic compound derived from abamectin (avermectin B_1) a fermentation product of *Streptomyces avermitilis* by selective hydration with chlorotris(triphenylphosphin)rhodium (I) (Wilkinson catalyst) [26–28].

In *human medicine* ivermectin is the drug of choice for onchocerciasis (river blindness) although it only kills *Onchocerca volvulus* micro-

filariae and not the adults. Although the drug has no curative effect, a single dose of 0.2 mg per kilogram body weight every 6 – 12 months controls the disease [29]. The drug is under clinical development for treatment of intestinal nematode infections (*Ascaris*, *Enterobius*, *Trichuris*, *Strongyloides*, and *Trichinella spiralis*).

In *veterinary medicine* ivermectin is used in cattle against a wide variety of nematodes and arthropods. It is inactive against cestodes and trematodes.

Occasional *adverse effects* in humans include headache, fever, pruritus, oedema, and arthralgies. However, as ivermectin is used only 1 – 2 times a year at low dosages, side effects are rare. Veterinary usage has shown that collies are particular sensitive in developing gabergic side effects (CNS depression with dizziness, ataxia, tremor, salivation, mydriasis, and coma with exitus).

Presumably, ivermectin exerts its mode of action by interfering with GABA, glutamate or glycine gated chloride channels, all of which are inhibitory neurotransmitters [30–32]. This action leads to an increased permeation of chloride ions, followed by a hyperpolarization of nerve-muscle membranes and a flaccid paralysis of the parasites. The action of ivermectin can be antagonised by bicuculline and picrotoxin [33].

Trade names: Mectizan in France (MSD), Ivomec (MSDAGVET).

Levamisole [*16595-80-5*], L(−)−2,3,5,6-tetrahydro-6-phenylimidazo[2,1-*b*]thiazole hydrochloride, $C_{11}H_{12}N_2S \cdot HCl$, M_r 240.8, *mp*227 – 229 °C, is a colorless, odorless, crystalline solid. It is soluble in water and slightly soluble in chloroform.

The compound is synthesized by the reaction of 4-phenyl-2-thioimidazoline with dibromoethane [34].

Levamisole is used against roundworm (*Ascaris*) infections. It is less effective against *Ancylostoma, Necator*, or *Strongyloides.* Occasional adverse reactions are nausea, vomiting, abdominal discomfort, headache, dizziness, hypertension.

Levamisole causes rapid spastic contraction in nematodes by persistently depolarizing the muscle-cell membrane. It also acts as a ganglion-stimulating compound [35]. The paralyzed nematodes are then eliminated from the intestine. Levamisole is likely to be hydrolyzed to L(−)−2-oxo-3-(2-mercaptoethyl)−5-phenylimidazoline under alkaline conditions. This metabolite is a strong and stereospecific inhibitor of the enzyme fumarate reductase through its interaction with −SH groups of the active center.

Trade names: Ascaridil, Decaris, and Stimamizol (Johnson & Johnson, Janssen); Ketrax (ICI); Solaskil (Specia).

Mebendazole [*31431-39-7*], methyl(5-benzoyl-1*H*-benzimidazol-2-yl)carbamate, $C_{16}H_{13}N_3O_3$, M_r 295.3, *mp* 288.5 °C, is an off-white amorphous powder. It is insoluble in water, sparingly soluble in dimethylformamide or dimethyl sulfoxide, and soluble in formic acid.

The compound is synthesized by the reaction of 3,4-diaminobenzophenone hydrochloride with *N*-carboxymethyl-*S*-methylisothiourea [36].

Mebendazole is used against nematode infections: *Ascaris, Trichuris, Enterobius, Ancylostoma, Necator, Capillaria.* It is also effective against tapeworms (*Taenia*). Occasionally adverse reactions, abdominal pain and diarrhea, occur. A rare complication is leukopenia. Pregnancy is a contraindication.

Mebendazole interferes with glucose uptake by nematodes and cestodes in vivo and in vitro. This interference occurs by the selective interaction with intracellular tubulin and subsequent inhibition of the assembly of microtubules. The microtubules participate in several important cell functions, e.g., the transport of materials within cells [37].

Trade name [18]: Vermox (Janssen, Ortho).

Metrifonate [*52-68-6*], *O,O*-dimethyl-2,2,2-trichloro-1-hydroxyethylphosphonate, $C_4H_8Cl_3O_4P$, M_r 257.4, *mp* 83 – 84 °C, is a colorless, crystalline solid. It is soluble in water, chloroform, or ether and very slightly soluble in pentane or hexane.

The compound is synthesized by reaction of chloral with dimethyl phosphite [38].

Metrifonate is used against the blood fluke *Schistosoma haematobium.* The occasional adverse reactions are nausea, vomiting, bronchospasm, weakness, diarrhea, and abdominal pain.

In vivo, metrifonate rapidly rearranges to *O,O*-dimethyl *O*-(2,2-dichlorovinyl) phosphate, which is a potent inhibitor of schistosome acetylcholinesterase. This paralyzes the parasites because of the accumulation of acetylcholine, which functions as inhibitory transmitter [39].

Trade name: Bilarcil (Bayer).

Niclosamide [*50-65-7*], 2′,5-dichloro-4′-nitrosalicylanilide, $C_{13}H_8Cl_2N_2O_4$, M_r 327.5, *mp* 225 – 230 °C, is a tasteless, pale yellow, crystalline solid. It is almost insoluble in water; sparingly soluble in ethanol, chloroform, or ether; and soluble in acetone.

The compound is synthesized by condensation of 5-chlorosalicylic acid with 2-chloro-4-nitroaniline [40].

Niclosamide is used against all kinds of tapeworms. It is also effective against intestinal flukes. Occasional adverse reactions are abdominal pain and nausea.

Niclosamide causes uncoupling of oxidative phosphorylation and respiration. It also activates ATPases, and this disturbs the energy balance of cestodes, which degrade endogenous glycogen, and impairs glucose uptake. Protein synthesis is also affected; e.g., a trypsin inhibitor is no longer formed, which facilitates proteolytic attack of the tapeworm by host digestive enzymes [41].

Trade names: Yomesan, Cestocide, and Nasemo (Bayer); Niclocide (Miles); Trédémine (Roger Bellon); Radeverm (VEB Arzneimittelwerk Dresden); Sulqui (Ella); Atenase (ICN Usafarma); Teniarene (Amsa); Teniamida (Bial); Fedal Telmin (Hosbon-Fedal); Copharten (Cophar). Some preparations contain niclosamide monohydrate.

Niridazole [*61-57-4*], 1-(5-nitro-2-thiazolyl)-2-imidazolidinone, $C_6H_6N_4O_3S$, M_r 214.2, *mp* 260 – 262 °C, is a yellow, crystalline solid. It is almost insoluble in water and most organic solvents, but it is soluble in dimethylformamide.

The compound is synthesized by reaction of 2-amino-5-nitrothiazole and β-chloroethylisocyanate [42].

Niridazole can be used against blood flukes, especially *Schistosoma haematobium.* Tolerance and efficacy are reduced in *S. mansoni* and especially in *S. japonicum* infections. It is also used in *Dracunculus* infections. Immunosuppression, vomiting, cramps, dizziness, and headache are among the frequent adverse reactions. Occasional adverse reactions are diarrhea, electrocardiographic changes, rash, insomnia, and paresthesia. Psychosis, hemolytic anemia, and convulsions are rare. Contraindications are impaired liver function, glucose-6-phosphatedehydrogenase deficiency, epilepsy, and severe heart diseases.

Niridazole causes a depletion of glycogen in schistosomes by inducing a reduced rate of conversion of active glycogen phosphorylase to its inactive form. This is achieved through inhibition of the enzyme phosphorylase phosphatase, which normally inactivates glycogen phosphorylase. It is possible that the active moiety is not niridazole, but its 5-imino analog, which can be formed by schistosomes in vitro under anaerobic conditions [43].

Trade names: Ambilhar (Ciba-Geigy); Ambilhar Ciba (Biogalenica Q Farm).

Oxamniquine [*21738-42-1*], 1,2,3,4-tetrahydro-2-[(isopropylamino)methyl]−7-nitro-6-quinolinemethanol, $C_{14}H_{21}N_3O_3$, M_r 279.3, *mp* 151 – 152 °C, is a light orange, crystalline solid. It is slightly soluble in water and soluble in methanol, acetone, or chloroform.

The compound is manufactured by fermentative oxidation of its 6-methyl analog by *Aspergillus scleroticum* [44].

Oxamniquine is used against the blood fluke *Schistosoma mansoni.* The adverse reactions observed are vertigo, vomiting, nausea, abdominal pain, anorexia, dizziness, drowsiness, and somnolence. Hallucinations are occasional, and epileptiform convulsions are rare. Intramuscular injection causes severe pain at the site of injection.

The antischistosomal effect of oxamniquine as a function of time correlates well with the activity of the enzyme ornithine-δ-transaminase. The enzyme may interfere with normal arginine formation and the maintenance of a normal nitrogen balance in the parasite [43].

Trade names: Mansil, Vansil, and Vancil (all Pfizer).

Oxantel [*68813-55-8*], (*E*)−3-[2-(1,4,5,6-tetrahydro-1-methyl-2-pyrimidinyl)ethenyl]-phenol 4,4′-methylenebis(3-hydroxy-2-naphthalenecarboxylate), $C_{36}H_{32}N_2O_7$, M_r 604.7, *mp* 207 – 208 °C (hydrochloride), is a yellow crystalline solid. It is practically insoluble in water.

It is synthesized by condensation of 3-hydroxybenzaldehyde and 1,2-dimethyl-1,4,5,6-tetrahydropyrimidine in refluxing ethyl formate [45].

The cation is the active part of the compound. Oxantel is used against whipworm (*Trichuris*). No adverse reactions to this relatively new drug have been found, but it can be expected to behave much like the closely related pyrantel.

Trade name: Telopar (Pfizer).

Piperazine [*110-85-0*], piperazine hexahydrate, $C_4H_{10}N_2 \cdot 6\,H_2O$, M_r 194.2, *mp* 43 – 45 °C, is a colorless salty tasting crystalline solid. It is soluble in water and insoluble in ether.

Piperazine is used against roundworms (*Ascaris*) and pinworms (*Enterobius*). Adverse reactions are nausea, vomiting, diarrhea, abdominal pain, headache, and paresthesia. Urticaria may occur occasionally. Contraindications are impaired renal or hepatic function. Various salts are also used: Calcium ethylenediaminetetraacetate (edetate), calcium citrate, citrate, tartrate, maleate, phosphate, adipate, sebacate, sulfate. Piperazine increases the resting potential of the somatic musculature of nematodes, especially in the syncytial region, by increasing the permeability of the membrane to chloride ions. This results in flaccid paralysis of the parasites, which are expelled from the intestine [17].

Trade names [18]: Uvilon (Bayer); Antepar 1953 (Wellcome); Helmazine (Midy); Multifuge (Glaxo); Neox (Rocador).

Praziquantel [*55268-74-1*], 2-cyclohexylcarbonyl-1,2,3,6,7,11 *b*-hexahydro-4*H*-pyrazino[2,1-*a*]isoquinolin-4-one, $C_{19}H_{24}N_2O_2$, M_r 312.4, *mp* 136 – 140 °C, is a bitter tasting, colorless, crystalline solid. It is sparingly soluble in water and soluble in ethanol, chloroform, or dimethyl sulfoxide.

The compound is synthesized by reacting 1,2,3,6,7,11 *b*-hexahydropyrazino[2,1-*a*]isoquinolin-4-one with cyclohexylcarbonyl chloride in chloroform [46].

Praziquantel is used against all infections caused by trematode parasites (blood, liver, lung, and intestinal flukes) or adult tapeworms. It is also effective in cysticercosis. Occasional adverse reactions are epigastric pain, nausea, dizzi-

ness, diarrhea, and vomiting. Rare adverse reactions are skin manifestations, headache, and tiredness.

Praziquantel causes a very rapid increase in the permeability of membranes to divalent cations. In the musculature of trematodes and cestodes, this permeability increase results in a calcium concentration increase, which initiates rapid contracture and subsequent spastic contraction and paralysis. In the tegument, praziquantel causes rapid and progressive vacuolization, which leads to partial disintegration of the body surface of the parasites. This, in turn, renders them susceptible to attacks by the host defense system and its digestive enzymes [47].

Trade names: Biltricide (Bayer, Miles); Cestox, Cesol, and Cisticid (all E. Merck).

Pyrantel [*22204-24-6*], (*E*)−1,4,5,6-tetrahydro-1-methyl-2-[2-(2-thienyl)vinyl]-pyrimidinium 4,4′-methylenebis(3-hydroxy-2-naphthalenecarboxylate), $C_{34}H_{30}N_2O_6S$, M_r 594.7, *mp* 178 – 179 °C (free base), is a tasteless, odorless, yellow, crystalline solid. It is insoluble in water, slightly soluble in dimethylformamide, and soluble in dimethyl sulfoxide.

The compound is synthesized by reacting 2-thiophenealdehyde with 1,2-dimethyltetrahydropyrimidine [48].

The cation is the active part of the compound. Pyrantel is used against nematodes: *Ascaris, Enterobius, Ancylostoma*, and *Necator.* Adverse reactions are anorexia, abdominal cramps, diarrhea, nausea, vomiting. Occasional adverse reactions are headache, dizziness, drowsiness, and skin rash. Impaired hepatic function is a contraindication.

Pyrantel is a depolarizing neuromuscular blocking agent. In nematodes it causes a slowly developing contraction and paralysis. The immobilized parasites are then eliminated from the intestine. The neuromuscular junction of *Ascaris* is 100-fold more sensitive to pyrantel than to acetylcholine [49].

Trade names: Lombpiareu (Areu); Aut (Elea); Aguipiran (Aguilar); Tamoa (North Medicamenta); Antiminth (Roerig); Combantrin, Trilombrin, Cobantril, and Helmex (Pfizer); Tricocel and Piranver (ICN Usafarma); Verdal (Columbia); Perverme (Biofarma); Piranver and Piranver F (ICN Farmaceutica).

Pyrvinium [*3546-41-6*], 6-(dimethyl-amino)-2-[2-(2,5-dimethyl-1-phenyl-1*H*-pyrrol-3-yl)-ethenyl]−1-methylquinolinium 4,4′-methylenebis(3-hydroxy-2-naphthalenecarboxylate), $C_{75}H_{70}N_6O_6$, M_r 1151.4, *mp* 210 – 215 °C, is a tasteless, odorless, bright orange to black, crystalline solid. It is insoluble in water or ether, slightly soluble in chloroform, and soluble in glacial acetic acid.

The compound is synthesized by the reaction of 1,2-dimethyl-6-dimethylaminoquinoline iodide with 2,5-dimethyl-1-phenyl-3-pyrrolaldehyde [50].

The cation is the active part of the compound. Pyrvinium is used against pinworms (*Enterobius*). Occasional adverse reactions are blood dyscrasia and folic acid deficiency. Rare adverse reactions are rash, vomiting, convulsion, shock, photosensitivity, and headache.

Trade names: Vanquil, Vanpar, Vanquin, Povan(yl) Molevac, Povan 1959, Paquil, Polyquil, and Povanyl (all Parke-Davis and Substantia).

Suramin [*129-46-4*], hexasodium 8,8′-[carbonylbis[imino-3,1-phenylenecarbonyl-imino(4-methyl-3,1-phenylene)carbonyl-imino]]bis-1,3,5-naphthalenetrisulfonate, $C_{51}H_{34}N_6Na_6O_{23}S_6$, M_r 1429.2, is a pinkish white, white, or cream-colored, odorless, hygroscopic powder with a slightly bitter taste. It is soluble in water and insoluble in chloroform or ether.

The compound is synthesized by condensation of 1-naphthylamine-4,6,8-trisulfonic acid with 3-nitro-4-methylbenzoyl chloride, reduction of the product, condensation with 3-nitrobenzoyl chloride, renewed reduction, and final condensation with phosgene [51].

Suramin is used as a macrofilaricide against *Onchocerca.* Frequent adverse reactions are nausea, vomiting, colic, and urticaria. Occasionally, kidney damage, blood dyscrasias, shock, and optic atrophy occur. Allergic reactions to filarial proteins (pruritus, rash, fever, edema, hyperesthesia, photophobia, lachrymation) are also encountered.

The mechanism of action is not well understood. Suramin inhibits many different enzyme systems by binding to free cationic amino acid residues in the area of the active center. This appears to lead to a specific, but slight, interference with the DNA-RNA replication mechanism. The inhibition of protein kinase, an enzyme intimately involved in intracellular regulation, also may be involved in the effects of suramin [52].

Trade names: Germanin (Bayer); Antrypol (ICI); Moranyl (Specia).

Thiabendazole [*148-79-8*], 2-(4-thiazolyl)−1*H*-benzimidazole, $C_{10}H_7N_3S$, M_r 201.3, *mp* 304 – 305 °C, is a tasteless, colorless, crystalline solid. It is insoluble in water, slightly soluble in ethanol or chloroform, and soluble in acetone, dimethyl sulfoxide, or dimethylformamide.

The compound is synthesized by heating 4-thiazolecarboxamide with *o*-phenylenediamine in polyphosphoric acid [53].

Thiabendazole is used against nematodes and nematode larvae: *Enterobius, Ascaris, Strongyloides, Necator, Trichinella, Ancylostoma, Capillaria, Dracunculus*, and *Trichostrongylus.* It is also effective against intestinal flukes. Frequent adverse reactions are dizziness, anorexia, vomiting, and epigastric distress. Diarrhea, fever, headache, skin rashes, hallucinations, and olfactory disturbances occur occasionally. Tinnitus, hypotension, and syncope are rare complications. The mechanism of action is not yet understood. Thiabendazole inhibits fumarate reductase, an enzyme essential for mitochondrial energy production in many nematodes, but this cannot be the primary or sole mechanism. Possibly thiabendazole, like mebendazole, affects tubulin polymerization, but there is no good experimental evidence for this [43].

Trade names: Mintezol and Minzolum (Merck Sharp & Dohme).

Anthracene [*120-12-7*], $C_{14}H_{10}$, was discovered in coal tar by J. Dumas and H. A. Laurent in 1832.

1. Physical Properties

Anthracene, $C_{14}H_{10}$, M_r 178.24, *mp* 218 °C, *bp* 340 °C (at 101.3 kPa), $d_4^{25} = 1.252$ colorless plates with blue-violet fluorescence, sublimes readily and forms a continuous series of mixed crystals with phenanthrene and carbazole in binary and ternary systems. Anthracene is slightly soluble in benzene, chloroform, and carbon disulfide; less soluble in diethyl ether and ethyl alcohol; and almost insoluble in water.

Specific heat capacity	1164 J/kg (at 24 °C)
Heat of fusion	162 kJ/kg
Heat of vaporization	294 kJ/kg
Heat of combustion	40110 kJ/kg (at 25 °C)

2. Chemical Properties

Anthracene is converted to dianthracene by irradiation with UV light in the absence of oxygen. In the presence of oxygen anthracene is converted to a peroxide by addition of oxygen to the 9,10-positions. Pyrocondensation gives 2,9-bianthryl and 9,10-dihydroanthracene [5]. Anthracene is readily hydrogenated to 9,10-dihydroanthracene. With homogeneous ruthenium catalysts, anthracene is hydrogenated to 1,2,3,4-tetrahydroanthracene [6]; further hydrogenation yields 1,2,3,4,5,6,7,8-octahydroanthracene. Oxidation of anthracene in the liquid or gas phase gives anthraquinone (→ Anthraquinone). Anthracene is primarily halogenated and nitrated in the 9- and 10-positions, and sulfonated in the 1- or 2-position, depending on the reaction conditions. Anthracene undergoes Diels – Alder addition of maleic anhydride and other dienophiles in the 9- and 10-positions.

With magnesium metal in THF anthracene undergoes an addition reaction to form a magnesium – anthracene adduct from which highly reactive magnesium can be obtained that can be converted to magnesium hydride and Grignard reagents [7].

3. Production

High-temperature coal tar contains, on average, 1.5 % of anthracene. Continuous tar distillation concentrates the anthracene in the fraction boiling between 300 and 360 °C (anthracene oil I). This oil amounts to 15 – 20 % of the raw tar and contains about 7 % anthracene; it is cooled to 20 – 30 °C and then centrifuged. About 10–15 % of the crude anthracene oil I is obtained as a yellow-green crystalline material with an anthracene content of 20 – 35 % (anthracene residues). These residues, which also contain 40 – 50 % phenanthrene and 12–20 %

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a02_343.pub2

carbazole, are crystallized or distilled. Distillation yields a crude product containing 45 – 55 % anthracene (50s anthracene). A 50s anthracene with an improved quality can be produced by two-step continuous column distillation [8, 9]. The crude 50s anthracene then is purified by recrystallization from selective solvents and by distillation. Repeated recrystallization from a three- to fourfold excess of pyridine produces anthracene (95 % purity) from the 50s anthracene in 80 % yield relative to the anthracene content. Other selective solvents suitable for recrystallization are acetone [10 – 14], acetophenone [15], benzene – methanol [16], dialkyl sulfoxides [17], dialkylformamides [18], *N*-methylpyrrolidone [19], dimethylacetamide [20], and propylene carbonate [21].

High yield of anthracene (96 %) and low energy consumption can be achieved by solvent-free, high-temperature melt crystallization of anthracene residues or anthracene oil I [22, 23].

Anthracene can be separated from the higher-boiling carbazole by distillation with lower-boiling hydrocarbon fractions as reflux medium [24, 25] or by azeotropic distillation with ethylene glycol [26, 27]. Azeotropic distillation also is used to separate the anthracene-accompanying tetracene and to obtain very pure anthracene for scintillation counting [28].

In principle, anthracene is also available from the high-boiling oil of coal liquefaction [29].

Carbazole-free crude anthracene can be prepared by distillation and crystallization of residues obtained from the pyrolysis of hydrocarbon fractions to olefins; however, the anthracene content of these pyrolysis oils generally is less than 1 % [30]. The anthracene yield can be increased by selective hydrodealkylation of the aromatic fraction containing methylphenanthrenes and methylanthracenes [31].

Anthracene can be synthesized by hydrogenation of phenanthrene, isomerization of the resulting *sym*-octahydrophenanthrene to *sym*-octahydroanthracene, and subsequent dehydrogenation [32 – 35]. A mixture of *sym*-octahydroanthracene and *sym*-octahydrophenanthrene is obtained by catalytic disproportionation of tetralin [36 – 38]. In addition, anthracene is formed from diphenylmethane in the presence of HF/BF_3 at 80 °C [39, 40] and by thermal reaction of *o*-methyldiphenylmethane at ca. 600 °C [41]. These syntheses have no commercial importance to date because sufficient anthracene is obtained from coal tar.

4. Analysis

Anthracene is determined quantitatively in the presence of other coal tar constituents by oxidation with chromic acid in glacial acetic acid to produce anthraquinone; by Diels – Alder reaction with maleic anhydride [42, 43]; by gas chromatography [44]; by UV spectroscopy [45, 46]; or by luminescence spectroscopy [47].

5. Uses

On a commercial scale, about 10 000 t/a of anthracene is used, almost exclusively for the production of anthraquinone (→ Anthraquinone). The use of anthracene as a plasticizer for thermosetting resins and as a light stabilizer for polymers has been proposed. The use of anthracene derivatives as building blocks for engineering plastics was also suggested. The polyether of 9,10-dihydoxyanthracene is an example [48]. Anthracene is a crystalline organic photoconductor that can be used in electrophotography. In its purest form, anthracene is frequently employed as a scintillant to detect high-energy radiation, e.g., in nuclear physics.

6. Toxicology and Environmental Aspects

Toxicology. As a polycyclic aromatic hydrocarbon, anthracene is suspected to be carcinogenic [49, 49, 50, 50, 51, 51 – 56]. This earlier experience involving workers is based on crude anthracene that was contaminated with various other polycyclic aromatic hydrocarbons. Pure anthracene, however, has no appreciable carcinogenic effect under experimental conditions [54, 57 – 59]. This is underlined by consistently negative findings in numerous in vitro and in vivo genotoxicity tests [58, 59]. Only subcutaneous injections of an oily solution containing 20 mg of anthracene, given 33 times at the rate of one per week, resulted in local development of fibroma, to some extent with sarcoma-like excrescences [54, 55]. An epicutaneous tumor initiation test conducted over 35 weeks on mice

Table 1. Photoinduced anthracene toxicity

Test organism	Effective concentration		Exposure to UV light		Ref.
	Type (total test duration)	Value, mg/L	Intensity, μW/cm^2	Time	
Selenastrum capricornutum (alga)	NOEC (36 h)	0.0015 – 0.003	A 410 – 765	22 h	[94]
Daphnia magna (crustacea)	NOEC (21 d)	ca. 0.002	A 117	16 h/d	[95, 96]
Juvenile bluegill (freshwater fish)	LC_{100} (24 – 72 h)	0.012	sunlight (Oct.)	day-night cycle	[93]
Juvenile bluegill (freshwater fish)	LC_{50} (96 h)	0.0012	B 170	96 h	[92]
Fathead minnow larvae (freshwater fish)	LC_{50} (40 h)	0.0054	A 95	16 h	[97]
Fathead minnow (freshwater fish)	NOEC (9 weeks)	<0.0066	none		[90]

with pure anthracene and phorbol ester as promoter resulted in papilloma in a few cases (4 out of 28 animals) [60]. Anthracene is classified as "not classifiable as to its carcinogenicity to humans" by IARC (Category 3) and by EPA (Group D) [59].

Peroral application of 1.7 g/kg of pure anthracene has no lethal effect on mice [61]. Anthracene is absorbed percutaneously: after topical application of a ^{14}C-labeled solution in hexane or acetone (ca. 9 μg/cm^3) to rat skin, some 50 % was absorbed in 6 d (ca. 29 % was recovered from the urine, ca. 22 % from the feces, and ca. 1 % from tissue, mainly the liver and kidneys); after 1 d 20 % of the dose was already present in the urine (ca. 17 %) and feces (ca. 3 %) [62]. Anthracene can sensitize the skin locally to light [63]. Gerarde proposes a TLV of 0.1 mg/m^3 [56].

Environmental Fate and Toxicity. Anthracene is inherently biodegradable in water [64 – 67] and soil [68 – 72]. Most of the elimination half-lives found in experimental soil and water systems are below 180 d. In water – sediment mesocosm systems involving photolytic and biological processes, short residence times were observed with elimination rates of >98 to >99.5 % for the parent substance from the water phase within 17 and 40 d, respectively [73 – 75]. Several studies using [9-^{14}C]-radiolabeled anthracene gave evidence of partial mineralization of the parent compound during the observation period [64, 76, 77].

Photodegradation in air and water is rapid; measured elimination half-lives were between 2 and 4 h in air [78, 79] and less than 1 to ca. 40 h in water systems [64, 80 – 82].

The moderate to high water-partition coefficient (log P_{ow} 3.9 – 4.5) [74, 83, 84] indicates significant bioconcentration potential. This is low to moderate in fish [64, 74, 85 – 90] and daphnia [64, 87, 88, 91] with bioconcentration factors (BCF) generally ranging between ca. 700 and 5000.

Photoinduced aquatic toxicity of anthracene in aquatic organisms may be 2 – 3 orders of magnitude higher than in the absence of UV light and appears to depend on the accumulated body burden, as fish previously exposed to anthracene in the dark were void of any symptoms, but exhibited severe signs of distress or showed increased mortality when placed in clean water in the presence of UV light [92]. But also without prior or concurrent UV irradiation, chronic toxic effects of anthracene are reported to affect reproduction of fish at low concentrations [90].

Acute lethal concentrations (LC_{50}) and no-observed-effect concentrations (NOEC) are below 0.1 and 0.01 mg/L, respectively, and significantly lower than the water solubility of anthracene (see Table 1).

1. Introduction

Anthraquinone [*84-65-1*] is the parent compound for a large palette of anthraquinone dyes and so is the most important starting material in their production. Furthermore, anthraquinone is gaining importance as a catalyst in the pulping of wood.

1

In 1835, anthraquinone was prepared for the first time by LAURENT, via oxidation of anthracene, which at first went largely unnoticed. Its special importance for the dye industry was recognized only in 1868 when GRAEBE and LIEBERMANN prepared anthracene from alizarin (1,2-dihydroxyanthraquinone) and, in turn, alizarin via anthraquinone. This laid the groundwork for the synthesis route of this – at the time – important dye. Since then, science and technology have extended the chemistry of anthraquinone swiftly, first by the discovery of new mordant dyes and acid dyes, later by the introduction of vat dyes and disperse dyes, and, since 1950, by the anthraquinone reactive dyes. At the same time, anthraquinone chemistry has acted as a stimulus for the rapid extension of the production processes of chemicals, such as oleum and chlorine.

Since 1970, the industrial chemistry of anthraquinone has been undergoing a revolution worldwide. Initiated by a growing shortage of anthracene accompanied by an increasing demand, new procedures of synthesis using naphthalene or styrene as starting materials were developed. Moreover, further processing of anthraquinone is changing; α-substituted anthraquinones should no longer be prepared by mercury-catalyzed sulfonation but by new nitration procedures.

A completely new use for anthraquinone was established by HOLTON in 1977, when he discovered the catalytic effect of anthraquinone on the alkaline pulping of wood. This branch of anthraquinone chemistry is experiencing a rapid development and has good chances of outdistancing the needs of the dye industry. The demand for anthraquinone has risen continuously since 1870. At present the annual demand is $\approx 30\,000$ t.

2. Properties

Physical Properties. Anthraquinone [*84-65-1*], $C_{14}H_8O_2$, M_r 208.20, *mp* 287 °C, *bp* 377 °C, crystallizes as thin, light yellow to pale yellow needles; it is almost colorless if finely divided, as when precipitated from sulfuric acid. The faint colors of the crystals are effected strongly by the granular structure and in commercial products often are covered up by trace impurities.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a02_347

Crystallographic class: monoclinic, space group $P2_1/a$. Dimensions of the unit cell: $a = 1.583$ nm, $b = 0.397$ nm, $c = 0.789$ nm, $\beta = 102.5$

Density of the crystals at 20 °C: 1.438 g/cm^3, of the melt (at 293 °C): 1.067 g/cm^3

Vapor pressure: 10.0 kPa at 286 °C, 20.0 kPa at 300 °C, 48.0 kPa at 340 °C

Molar heat capacity at constant pressure c_p (solid) 265 J mol^{-1} K^{-1}

Enthalpy of formation −179 kJ/mol

Enthalpy of combustion at 25 °C: 6449 kJ/mol

Melting enthalpy at 287 °C: 32.57 kJ/mol

Flash point 185 °C

The UV spectrum exhibits four bands – 251 nm (ε_{max} 54000), 279 nm (ε_{max} 17600), 321 nm (ε_{max} 4800), and 377 nm (ε_{max} 110) – each with pronounced vibrational structure. Unlike solutions of anthracene, most solutions of anthraquinone do not show fluorescence. The IR spectrum has very few bands (characteristic bands at $\nu_{C\rightarrow O} = 1680\ cm^{-1}$) because of the high symmetry of the compound.

Anthraquinone is sublimed easily without decomposition, a property exploited industrially for purification.

Anthraquinone is practically insoluble in water (0.006 g/L at 50 °C) and nearly insoluble to sparingly soluble in organic solvents at room temperature. However, solubility in organic solvents increases with temperature (in ethanol 0.05 g per 100 g ethanol dissolves at 18 °C, 2.25 g per 100 g at 78 °C; in toluene 0.19 g per 100 g toluene at 15 °C, 2.56 g at 100 °C). Therefore anthraquinone generally can be recrystallized from high-boiling solvents, particularly from the polar solvents pyridine, aniline, nitrobenzene, formamide, or dimethylformamide. Anthraquinone dissolves in 90 % sulfuric acid giving a yellow to orange solution, and in oleum (20 % SO_3), giving a red solution. It can be precipitated from these solutions in a finely divided form by dilution with water. The solubility increases with the concentration of the sulfuric acid. Anthraquinone behaves similarly in hydrofluoric acid; however, the solubility in almost 100 % phosphoric acid is relatively small.

Anthraquinone can form explosive dust mixtures with air. Friction causes anthraquinone to become electrostatically charged.

Chemical Properties. Anthraquinone exhibits an extraordinary thermal stability, even in the presence of oxidizing agents. Therefore it can be prepared by oxidizing anthracene in the vapor phase. A yield of 90 % is obtained if conversion is complete.

Anthraquinone is attacked by oxidizing agents only under vigorous conditions. For example, it can be converted to alizarin by fusion with sodium hydroxide and sodium chlorate. Anthraquinone can be converted to the polyhydroxyanthraquinones alizarin, quinizarin, anthrarufin, and purpurine (→ Anthraquinone Dyes and Intermediates, Chap. 2.6.) by oxidation with concentrated sulfuric acid in the presence of boric acid, persulfates, or metaarsenic acid at temperatures generally above 200 °C. The oxidation can be carried out with oleum at a lower temperature that depends on the SO_3 content. Under the usual conditions, concentrated nitric acid does not oxidize anthraquinone, nitration taking place instead. Several mixtures of anthraquinone with 94 – 100 % nitric acid with specific anthraquinone concentrations are explosive.

On the other hand, anthraquinone can be reduced easily by ordinary reducing agents or by hydrogen in the presence of a catalyst. The standard potential (in aqueous ethanolic hydrochloric acid) for the anthraquinone–anthrahydroquinone equilibrium is only 0.155 V. Especially the quinone nucleus is reduced. Sodium hyposulfite in alkaline solution reduces anthraquinone to a blood-red sodium salt of anthrahydroquinone, which rearranges to its tautomer oxanthrone (9-keto-10-hydroxy-9,10-dihydroanthracene) in acidic solution. More vigorous reduction (tin – hydrochloric acid or catalytic hydrogenation at high pressure or high temperature) leads to anthrone (**2**) [*90-44-8*], which is in equilibrium with its tautomer anthrol (**3**) (9-hydroxyanthracene) [*529-86-2*], and then to anthracene and hydroanthracene.

If zinc or sodium hydroxide is used, dianthranol is obtained via dimerization.

The reduction can be restricted to the two outer nuclei by choice of reaction conditions. 1,2,3,4-Tetrahydroanthraquinone [*28758-94-3*] or octahydroanthraquinone [*23585-26-4*] can be obtained. Reactions of anthraquinone with the usual ketone reagents take place with great difficulty or not at all.

If anthraquinone is heated with glycerol, iron powder, and sulfuric acid, condensation takes place at positions 1 and 9, providing the commercially important benzanthrone [*82-05-3*] (→ Anthraquinone Dyes and Intermediates, Chap. 2.12.1.).

Chlorine halogenates anthraquinone in oleum in steps, depending on the proportion used, mainly at the α position. Heating anthraquinone with antimony pentachloride or a similar chlorine-releasing reagent produces chlorinated products, from monochloro- up to perchloroanthraquinone.

Sulfuric acid or oleum can sulfonate and/or hydroxylate anthraquinone. Concentrated sulfuric acid sulfonates only above 200 °C; usually, anthraquinone is sulfonated with 20 – 45 % oleum at 140 – 160 °C. The major reaction products are β-sulfonic acids, i.e., anthraquinone-2-sulfonic acid [*84-48-0*], as well as anthraquinone-2,6-disulfonic acid [*14486-58-9*], and anthraquinone-2,7-disulfonic acid [*84-49-1*]. In the presence of mercury, however, the sulfonation takes place almost exclusively at the α position, providing anthraquinone-1-sulfonic acid [*82-49-5*], anthraquinone-1,5-disulfonic acid [*117-14-6*], and anthraquinone-1,8-disulfonic acid [*82-48-4*].

The nitration of anthraquinone requires vigorous conditions, and provides mainly α-nitroanthraquinones along with 10 – 20 % β-nitro- and α,β-dinitroanthraquinones. Both mono- and dinitration take place, so that impure nitration products are obtained. These can be separated into 1-nitroanthraquinone, 1,5-dinitroanthraquinone, and 1,8-dinitroanthraquinone only by extensive processing. Trinitration of anthraquinone does not take place.

1-Nitroanthraquinone [*82-34-8*] can be prepared by nitrating anthraquinone in mixed acid (H_2SO_4-HNO_3) with excess nitric acid, in nearly 30 mol 94 – 98 % nitric acid, or with an almost stoichiometric amount of the mixed acid in the presence of chlorinated aliphatic hydrocarbons. The crude 1-nitroanthraquinone is purified by recrystallization and, if necessary, by distillation; likewise it is processed directly to crude 1-aminoanthraquinone [*82-45-1*], which is then purified by distillation.

1,5- and 1,8-dinitroanthraquinone are prepared by exhaustive nitration of anthraquinone in excess, nearly anhydrous mixed acid. Pure 1,5-dinitroanthraquinone [*82-35-9*] and 1,8-dinitroanthraquinone [*129-39-5*] are obtained by recrystallizing the crude dinitroanthraquinone mixtures from nitrobenzene (→ Anthraquinone Dyes and Intermediates, Chap. 2.4.).

3. Production

Processes that are used in the industrial production of anthraquinone:

1) Oxidation of anthracene with chromic acid
2) Vapor-phase oxidation of anthracene with air
3) Naphthalene process
4) Synthesis from phthalic anhydride and benzene

Anthraquinone is produced from anthracene, where this is available from coal tar, either by oxidation with chromic acid in 48 % sulfuric acid or by oxidation with air in the vapor phase. The oxidation with chromic acid is competitive, provided that the chromium(III) sulfate lye formed can be processed to tanning agents. Anthracene with purity of $\geqq$ 94 % is required for both oxidation processes; crude anthracene from coal tar must be purified by recrystallization.

About 85 % of world production is based on the oxidation of anthracene. Since the mid-1970s, anthracene production has fallen continuously, creating a supply shortage. Therefore, the complex naphthalene process is gaining in importance. There is an adequate supply of naphthalene in coal tar. If necessary, additional naphthalene can be isolated from the residual oils of gasoline reforming, a process common in the United States.

In the new naphthalene processes developed in Japan by Kawasaki and in Europe by Bayer anthraquinone is synthesized in three steps: Naphthoquinone is prepared by vapor-phase oxidation with air. Butadiene is added to this naphthoquinone in a Diels-Alder reaction. The tetrahydroanthraquinone formed is oxydehydrogenated. In this naphthalene process a significant

amount of phthalic anhydride byproduct is produced.

In the synthesis of anthraquinone from phthalic anhydride and benzene approximately 1.4 t of aluminum chloride and 4 – 6 t of sulfuric acid per ton of anthraquinone are used. This procedure is used in areas where anthracene is not available in sufficient amounts from coal tar. It may become important again, as a result of the shortage of anthracene. Phthalic anhydride has become available at low prices and in sufficient quantities following the introduction of the economical oxidation of naphthalene or *o*-xylene with air.

In the early 1970s another interesting anthraquinone process was developed by BASF. Styrene is first dimerized to 1-methyl-3-phenylindane in the presence of an acid catalyst, which is then converted to anthraquinone in the vapor phase by oxidation with air.

3.1. Oxidation of Anthracene with Chromic Acid

The classic process of oxidizing anthracene with chromic acid is still carried out industrially on a large scale. In combination with the manufacture of tanning agents this process involves virtually no expense for the oxidizing agent. The batch process is still in use.

Pure, finely pulverized 94 – 95 % anthracene (2600 kg) is pasted with water (9000 kg) in a 30000-L mixing vessel. A wetting agent is added. For oxidation, portions of 48 % sulfuric acid and 20 % sodium dichromate solution are added alternately; the reaction begins at 50 – 60 °C. The temperature increases to 100 – 105 °C but should not be allowed to increase any further. The temperature is controlled by regulating the amount of reagents added. Foaming is severe. A total of 10200 kg of 48 % sulfuric acid and 23 500 kg of 20 % sodium dichromate solution are used. At the end of the reaction there should be a small excess of oxidizing agent, which is reduced with hydrogen sulfite. The oxidation takes 30 – 36 h [4].

The reaction mixture is filtered through a suction filter while being stirred, washed, suspended with water, and filtered into a chambered rotary filter. A yield of ≈ 3000 kg of 95 % crude anthraquinone is obtained. The product is dried, or it is recrystallized from nitrobenzene, in which case the retained water is evaporated first. A purity of 99 % is achieved.

3.2. Vapor-Phase Oxidation of Anthracene with Air

The vapor-phase oxidation of anthracene with air was described first by A. Wolf in 1916. The catalysts are similar to those for the oxidation of naphthalene or *o*-xylene to phthalic anhydride: vanadium compounds, mainly iron vanadate [5] or vanadic acid doped with substoichiometric amounts of alkali metal or alkaline-earth metal ions [6].

The conversion of the anthracene is nearly quantitative. The major byproduct is a small quantity of phthalic anhydride, which is separated easily. The advantage of this procedure is that it produces anthraquinone of 99 % purity. It can be converted further without purification.

Details on a plant constructed by Aziendi Colori Nazionali Affini, Milan, were published [7]:

Anthracene is evaporated with a preheated air–water vapor mixture, and the gas current is mixed carefully with more air (danger of explosion!) and led into a catalytic furnace from the bottom at 325 °C. The catalytic furnace consists of 1400 L of catalyst piled in layers; temperature is controlled by tubes in which pressurized water circulates through these layers. The lower part of the furnace, where the reaction takes place, is cooled to 390 °C; the upper part is heated to 339 °C. The catalyst consists of iron vanadate prepared from ammonium vanadate and iron(III) chloride. The air flow rate is 2150 m^3/h, each

cubic meter containing 20 g of 94 % anthracene. The gases leaving the catalytic furnace first go through heat exchangers and then through cooling towers, cooling chambers, and dust filters. The anthraquinone produced has an average purity of 99.6 %

The iron vanadate catalyst is prepared as follows [5]: 2.4 kg of red iron(III) oxide is dissolved by heating it in 9.1 L of 30 % hydrochloric acid, 9.6 L of water, and 120 g of potassium sulfate. The resulting solution is mixed with a solution of 30.1 kg of ammonium vanadate in 600 L of water at 60 °C. The solution is made alkaline with ammonia and the water evaporated until precipitation begins. The pregnant iron vanadate solution is evaporated onto pumice at 110 – 130 °C in a heatable ball mill. The catalyst is calcined at 330 – 350 °C. The catalyst should be yellow brown but not dark brown.

After a period of time the activity of the catalyst falls off, resulting in a decline in the yield of anthraquinone and an increase in phthalic anhydride. To keep the activity of the catalyst constant or to reactivate it, a small amount of ammonia is added to the oxidation air or the exhausted catalyst is washed with a dilute alkali solution [8].

3.3. Naphthalene Process

The naphthalene process developed by Kawasaki Kasei Chemicals [9] consists of three steps. In the first step naphthalene is oxidized in the gas phase with air on a vanadium pentoxide catalyst to produce the relatively unstable naphthoquinone (**4**). Large amounts of phthalic anhydride form at the same time. Because most of the naphthalene reacts, recycling of unreacted naphthaline is not necessary [10–13].

The hot reaction mixture is precooled in a gas cooler and then quenched and washed with water in a tower. The naphthoquinone is obtained mixed with phthalic acid anhydride (or phthalic acid) as a suspension in water. The naphthoquinone is extracted with an aromatic solvent, for example xylene or tetrahydroanthraquinone, to separate it from the phthalic acid. The small residue of acid is carefully removed by washing with dilute alkali [14–16].

In the second step the naphthoquinone is

reacted with butadiene in a Diels-Alder reaction to give 1,4,4 *a*,10 *a*-tetrahydroanthraquinone (**5**). The Diels-Alder product is separated from unreacted naphthoquinone by extraction with aqueous alkali, which converts the quinone into a water-soluble alkali-metal salt. The organic phase, which contains naphthoquinone, is recycled to the first step [10], [11], [17].

In the third step the aqueous tetrahydroanthraquinone solution is reacted with air. The anthraquinone that forms is insoluble in aqueous alkali and can be isolated by filtration. The aqueous alkali is recycled into the tetrahydroanthraquinone extraction step [18]. The anthraquinone can be purified further by vacuum distillation [9].

Phthalic acid is isolated from the aqueous phthalic acid solution by crystallization and filtration. It is heated to convert it to phthalic acid anhydride. The phthalic acid anhydride can be further purified by distillation.

Kawasaki Kasei Chemicals operates a plant based on the naphthalene process that produces 3000 t/a. The plant has been in operation since 1980.

In Bayer's variation of the naphthalene process, naphthalene is oxidized with a mixture of air and recycled reaction gas on a vanadium pentoxide catalyst to give naphthoquinone, phthalic acid anhydride and unreacted naphthalene [19–21]. The products of the oxidation along with unreacted naphthalene are quenched and condensed into a liquid reaction mixture, which is reacted without purification with butadiene [22], [23]. The Diels-Alder product mixture that contains tetrahydroanthraquinone is reacted with air. The tetrahydroanthraquinone is

oxydehydrogenated to give anthraquinone. The naphthalene is removed by distillation [23–25]. The two end products, anthraquinone and phthalic acid anhydride, are separated by fractional distillation [26].

3.4. Synthesis from Phthalic Anhydride and Benzene

In the first step o-benzoylbenzoic acid (**6**) is prepared from phthalic anhydride and benzene by a Friedel-Crafts reaction. In the second step the *o*-benzoylbenzoic acid is cyclized to anthraquinone by heating with concentrated sulfuric acid. The primary product of the Friedel-Crafts reaction is an aluminum chloride complex of the *o*-benzoylbenzoic acid, which can harden easily to form a compact mass in the reaction vessel. Several methods have been proposed to overcome this problem. Based on a process described by G. HELLER already in 1906, condensation is carried out in excess benzene to give yields of more than 95 %. Patents issued to Klipstein & Sons and the I. G. Farbenindustrie from 1923 to 1927 describe a solvent-free process carried out in ball mills. The problem posed by the reaction mixture's baking can be reduced by adding ethylene glycol or 1,4-butanediol, which causes a reduction in the necessary excess benzene or makes a solvent-free process possible.

Phthalic anhydride, benzene, and aluminum chloride in a molar ratio of 1 : 1 : 2 are allowed to react below 45 °C in iron ball mills fitted with hollow axles for the addition of benzene and the removal of the hydrogen chloride formed during the reaction, or in a vessel equipped with a strong horizontal agitator, possibly propelled from the bottom. The reaction mass, which is heterogeneous at first, liquefies, then gradually becomes viscous as hydrogen chloride is continuously lost, and eventually forms a powder. During the reaction there is extensive foaming, producing several times the original volume, a fact that must be considered when the charge is measured out. The reaction is complete after 1 mol of hydrogen chloride per mol phthalic anhydride has been evolved. The reaction product is placed into dilute acid. The precipitated *o*-benzoylbenzoic acid is separated, washed, and dried, providing a yield of more than 95 %.

Pure *o*-benzoylbenzoic acid [*85-52-9*] crystallizes from water with 1 mol of water of hydration in triclinic crystals, *mp* 94 °C. The anhydrous acid crystallizes from xylene, *mp* 127 °C.

In the second step it is also possible to start with the aluminum chloride complex formed in the first step and cleave 1 mol of hydrogen chloride by heating to 200 °C. A good yield of anthraquinone is obtained. In practice, however, the condensation of the precipitated dried *o*-benzoylbenzoic acid with sulfuric acid is preferred.

The acid is dissolved in three to four times its weight in 95 – 98 % sulfuric acid and heated to 115 – 140 °C. The duration of heating depends on the quantity and concentration of the sulfuric acid and on the temperature. After completion of the reaction the anthraquinone is precipitated with water, filtered, and dried. A portion of the product also can be obtained in coarsely crystallized form by cooling the sulfuric acid solution directly. The yield is almost quantitative.

The condensation solution can be used directly for the manufacture of benzanthrone or anthraquinonesulfonic acids.

3.5. Styrene Process

This process was developed in pilot by BASF.

Styrene dimerizes in the presence of acid catalysts, such as sulfuric acid [27], [28], phosphoric acid, or boric acid [29], yielding primarily 1,3-diphenyl-2-butene, which cyclizes further on the same catalyst to 1-methyl-3-phenylindane [*6416-39-3*]. The yields obtained in this step are 85 – 90 %.

1-Methyl-3-phenylindane is converted directly to anthraquinone by oxidation with air in the vapor phase [30].

Basically, the same catalysts are used as those employed in the gas-phase oxidation of anthracene with air, i.e., vanadium compounds, primarily vanadium pentoxide in combination with other oxides, such as thallium oxide and antimony oxide [31].

Yields of ≈ 77 % are obtained in the oxidation stage. Byproducts are still attached to the precipitated reaction product, and further purification is necessary.

3.6. Environmental Considerations

Chromium salts should not get into the waste water from the chromic acid process. The chromium(III) sulfate lye is disposed of by processing it to tanning agents. The anthraquinone must be carefully washed free of chromium with small amounts of wash water.

In the gas-phase oxidation of anthracene with air and the naphthalene process, on the other hand, the emphasis is placed on purifying the large quantity of waste air.

The production of anthraquinone via the Friedel-Crafts reaction from phthalic anhydride and benzene is accompanied by a release of waste water containing 1.4 t of aluminum chloride and 4 – 6 t of sulfuric acid per ton of anthraquinone. Moreover, carcinogenic benzene must be eliminated from the waste air by thermal posttreatment.

4. Purification, Quality Requirements, and Analysis

Anthraquinone is most often purified by recrystallization, preferably from nitrobenzene. Other purification methods include sublimation or vacuum destillation.

At present, a degree of purity of at least 99 % is required for the major uses of anthraquinone, i.e., production of nitroanthraquinones and anthraquinonesulfonic acids. A content of 98 – 99 % is sufficient for use as catalyst in wood pulping. The admission of anthraquinone by the U.S. Food & Drug Administration (FDA) as catalyst in the manufacture of food packing paper requires a content of at least 98 % [32].

Today the main method of analyzing the content is gas chromatography: The other components and solvents, which are present in ppm quantities, are detected directly. High-pressure liquid chromatography is another suitable method of analysis.

According to the classic analytical processes the content is determined (1) by reduction to soluble anthrahydroquinone, filtration, back-oxidation, and weighing out the filtered anthraquinone or (2) by separating the anthraquinone by column chromatography and analyzing the eluate by UV spectroscopy.

5. Uses

Anthraquinone serves as the basis for the production of a large number of acid and base dyes, vat dyes, disperse dyes, and reactive dyes (→ Anthraquinone Dyes and Intermediates).

Anthraquinone-1-sulfonic acid, anthraquinone-2-sulfonic acid, anthraquinone-1,5-disulfonic acid, and anthraquinone-1,8-disulfonic acid as well as 1-nitroanthraquinone, 1,5-dinitroanthraquinone, 1,8-dinitroanthraquinone, anthrone, and benzanthrone are prepared in the first processing step. For environmental reasons the production of anthraquinone-2-sulfonic acid and anthraquinone-1,5- and anthraquinone-1,8-disulfonic acids is being replaced increasingly by the production of 1-nitroanthraquinone and 1,5- and 1,8-dinitroanthraquinone.

In the second stage of processing, the sulfonic or nitro groups generally are replaced by ammonia, amine, chlorine, alcoholate, phenolate, or other nucleophilic agents or are reduced to an amino group. Some of the anthraquinone dyes, however, are prepared from anthraquinone derivatives. These are synthesized not from anthraquinone, but from smaller molecules.

On a small scale, anthraquinone is used in the manufacture of denaturants to protect seed

from crows, in the modification of stand oils, to brighten up colophoniy, and in the manufacture of hydrogen peroxide.

The paper and pulp industry is another rapidly expanding market for anthraquinone [33]. Anthraquinone is a redox catalyst in the production of pulp; the intermediate anthrahydroquinone catalyzes the alkaline hydrolysis of the polymeric lignin. When 0.03 – 0.05 % anthraquinone is added, the yield of pulp is increased 2.5 – 4 % and the cooking time is reduced up to 30 % [34].

The worldwide production capacity is adequate to cover the actual demand for anthraquinone [35].

6. Economic Aspects

The production capacity for anthraquinone worldwide is at present 34000 t/a. About 50 % of this capacity is in Western Europe.

The most important manufacturers of anthraquinone and their production capacities are listed in Table 1.

Table 1. Anthraquinone production capacities [32], [35]

Western Europe	
Bayer	11000 t/a
ICI	2500 t/a
Ciba-Geigy	2200 t/a
ACNA	1000 t/a
Ugine Kuhlmann	800 t/a
L. B. Holliday	200 t/a
Yorkshire Chem.	200 t/a
	17900 t/a
United States	
Toms River Chem.	1500 t/a
American Cyanamid	400 t/a
	1900 t/a
Japan	
Kawasaki Kasei	3000 t/a
Nihon Joryn Kogyo	2000 t/a
	5000 t/a
Eastern Europe	
USSR	2600 t/a
Poland	1800 t/a
Czechoslovakia	1200 t/a
	5600 t/a
Other Countries	
Indian Dyestuff	3000 t/a
Amar Dye (India)	250 t/a
China	400 t/a
	3650 t/a
Worldwide	34050 t/a

7. Toxicology

Based on present knowledge, anthraquinone, unlike the "emodins" (hydroxyanthraquinone glycosides) from anthraquinone drugs [36], is biologically completely "inert," i.e., inactive, presumably as a consequence of its insolubility in water and lipids.

There is no toxicologic information about anthraquinone. Even in the *Toxic Substances List* [37] no LD_{50} is found for anthraquinone. In contrast to benzoquinone, which causes severe local irritation and is included in the list of occupational hazards because of its damaging effect on the cornea, a fine dust of anthraquinone to which emulgators were added had no greater effect on the eyes of rabbits than a talcum suspension, as was shown in a BASF study.

An MAK value of 10 mg/m^3 was recommended [38]; therefore, anthraquinone dust is considered the same as inert dust.

1. Introduction and History

The elucidation of the structure of alizarine by C. Graebe and C. Liebermann in 1868 marks the beginning of anthraquinone chemistry. After Caro, Graebe, and Liebermann had worked out a commercial synthesis for alizarine, major efforts, especially by R. Bohn (Badische Anilin- & Sodafabrik) and R. E. Schmidt (Farbenfabriken Bayer, formerly Friedrich Bayer & Co.) were directed toward the manufacture of hydroxyanthraquinones. A sizeable collection of red, blue, and green mordant dyes was assembled over a span of 20 years. The turn of the century saw the development of the first acidic anthraquinone dyes that could be used to dye wool in fast red to green shades without the need for pretreatment with mordants.

In 1901 a new era of anthraquinone chemistry started with the discovery of the mercury-catalyzed α-sulfonation of anthraquinone. (Substituted anthraquinones are usually designated as α for substitution at positions 1, 4, 5, or 8 and as β for substitution at positions 2, 3, 6, or 7. For example, α,α'-anthraquinonedisulfonic acid is a mixture of anthraquinone-1,5 and 1,8-disulfonic acids.) About 80 % of the anthraquinone dyes are still prepared via anthraquinonesulfonic acids, even though emphasis is shifting at present toward synthesis via nitroanthraquinones. Important early reactions of anthraquinone chemistry include the Fischer reaction (replacement of a sulfonic acid group by chlorine) and high-pressure fusion with lime (replacement of sulfonic acid by a hydroxy group).

Simultaneously, new fundamental developments took place in the area of anthraquinone vat dyes, e.g., indanthrone, flavanthrone, violanthrone, benzoylaminoanthraquinones, anthrimides, and anthrimidecarbazoles. Subsequent work concentrated on closing gaps in the offerings of vat and acid dyes and testing of potential applications in nontextile dye applications.

The introduction of synthetic fibers, such as polyester, polyamide, and polyacrylonitrile fibers, initiated a new phase in the development of anthraquinone dyes. This led to a number of substitution products of anthraquinone that were useful as disperse dyes or as basic dyes. With the appearance of the first fiber-reactive dyes, work on acid anthraquinone dyes was intensified.

A new application for vat dyes constituted their use as organic pigments. Based on these insights, a whole new series of specialty pigments was developed.

The synthesis of an anthraquinone dye generally involves a large number of steps. For example, the preparation of a vat dye may require as many as eight steps and may necessitate the preparation of seven different anthraquinone intermediates.

Anthraquinone dyes are surpassed in importance only by azo dyes. The more complicated syntheses and lower tinctorial strengths of the anthraquinone dyes make production costs higher than for azo dyes. Therefore anthraquinone dyes tend to be used only when the required properties and color fastness are extreme or when the colors desired are not obtained easily with azo dyes (especially bright blue to turquoise shades). Use of a dye in vat dyeing requires the presence of special structural features (quinoid or indigoid). Therefore most vat dyes are derived from anthraquinone.

2. Methods of Production

The production of anthraquinone intermediates and anthraquinone dyes generally proceeds from a few key products generated by electrophilic substitution of unsubstituted anthraquinone or by synthesis of the nucleus. The major methods employed to prepare anthraquinone derivatives substituted in the α position are sulfonation and nitration. Preparation of β-substituted anthraquinones and of quinizarin (1,4-dihydroxyanthraquinone) generally is accomplished by synthesis of the nucleus starting from phthalic anhydride and a benzene derivative.

Until fairly recently, preparation of almost 80 % of all important anthraquinones was based on anthraquinonesulfonic acids. However, nitration of anthraquinone is gaining in importance presently, a development triggered mainly by environmental considerations (e.g., production of large volumes of waste dilute acids during anthraquinone sulfonation). However, great progress has been made recently in solving the problems associated with sulfonation.

Preparation of nearly all important anthraquinones starts from the following key inter-

mediates: anthraquinonesulfonic acids, nitroanthraquinones, and the products of nucleus synthesis, 1,4-dihydroxy-, 2-methyl-, or 2-chloroanthraquinone. The only exceptions are derivatives with condensed rings, e.g., benzanthrone and derived products, which are prepared directly from anthraquinone via anthrone.

2.1. Anthraquinonesulfonic Acids

Anthraquinonesulfonic acids generally are obtained by sulfonation. Additional options, such as displacement of substituents (e.g., chlorine atoms or nitro groups) by sulfite or oxidation of mercapto groups, are of little importance but are used for the preparation of some substituted anthraquinonesulfonic acids.

The sulfonic acid group in anthraquinone enters readily into nucleophilic exchange reactions, whereby the α position is much more reactive than the β position. Sulfonic acid groups are exchanged readily against amino, alkylamino, hydroxy, and alkoxy groups. Exchange against chlorine atoms also proceeds smoothly (Fischer synthesis, see page 4).

Reduction also may be used to remove the sulfonic acid group from certain substituted anthraquinones, as, for example, from 1-amino-4-arylaminoanthraquinone-2-sulfonic acid.

Desulfonation of the α position may be accomplished by heating in 70 – 90 % sulfuric acid in the presence of mercury. This method is used to convert unnecessary α,α'-disulfonic acids back to anthraquinones [15], [16].

Sulfonation of the β position of anthraquinone is at present of little importance, because β-substituted compounds (e.g., 2-aminoanthraquinone) are prepared nowadays from 2-chloroanthraquinone instead of the sulfonic acid.

Process Details. Sulfonation of anthraquinones requires extreme conditions ($\approx 150\,^{\circ}$C, 20 % oleum), which yield either mono- or disulfonic acids, depending on the method of operation. Whereas nitration and halogenation preferentially substitute the α position, direct sulfonation attacks the β position, yielding anthraquinone-2-sulfonic acid or the 2,6- or 2,7-disulfonic acid derivatives.

If mercury or mercury compounds are added as catalysts, sulfonation proceeds under much milder conditions and substitution occurs preferentially at the α position. The mercury can be reclaimed during workup of the sulfonation mixtures [17–25].

Although other catalysts, such as palladium, ruthenium, or rhodium, are also suitable for sulfonating anthraquinone at the α position, they are not used industrially [26–28].

Anthraquinone-1-sulfonic acid [*82-49-5*], K salt, also called diamant salt, M_r 288.3, is prepared by sulfonation in the presence of, e.g., 0.5 % mercury in 20 % oleum, an amount of SO_3 adequate for the sulfonation of about 60 % of the charge. The reaction is controlled in such a manner that about 50 % of the anthraquinone remains unsulfonated. After mercury is precipitated as the sulfide, the unreacted anthraquinone is precipitated by dilution and is collected by filtration. After washing and drying, it is recirculated as ‘reclaimed quinone‘. Mercury is removed completely from the filtrate, and the anthraquinone-1-sulfonic acid is then precipitated as the potassium salt [23].

Anthraquinone-2-sulfonic acid [*84-48-0*], Na salt, also called silver salt, M_r 288.3, is prepared by sulfonation in the absence of mercury (e.g., according to the procedure cited in [3,

p. 8]). The acid also can be obtained from the 1,6- (or 1,7-) disulfonic acid by desulfonation at the α position in dilute sulfuric acid [15].

Anthraquinone-1,5-disulfonic acid [*117-14-6*], Thiol Acid, M_r 368.3, and anthraquinone-1,8-disulfonic acid [*82-48-4*], Azine Acid, M_r 368.3, are produced by disulfonation under conditions similar to those for monosulfonation except for an increased concentration of SO_3. After sulfonation of the anthraquinone is complete, the 1,5-acid is precipitated by slow addition of dilute sulfuric acid, collected, and washed with dilute sulfuric acid. The filter cake is dissolved in hot water, the solution treated with charcoal, and the anthraquinone-1,5-disulfonic acid precipitated from the filtrate as its disodium salt by addition of saturated sodium chloride solution. The 1,8-acid is isolated as the potassium salt from the sulfuric acid mother liquors and the wash acids (see also [1] and [3, p. 10]). Mercury can be removed in a similar manner as given for anthraquinone-1-sulfonic acid (see, e.g., [23]).

2.2. Alkyl- and Arylanthraquinones

Alkyl- and arylanthraquinones are obtained from the corresponding benzene derivatives and phthalic acid anhydride via the benzoylbenzoic acids.

2-Methylanthraquinone is of great importance for the synthesis of dyes. 2-Alkylanthraquinones (e.g., 2-ethyl-, 2-isoamyl-, or 2-*tert*amylanthraquinone) are used as oxygen carriers in the preparation of hydrogen peroxides (→ Peroxo Compounds, Inorganic). If α-haloanthraquinones are heated in the presence of copper in inert, high-boiling solvents, dimerization (Ullmann reaction) yields the corresponding 1,1′-dianthraquinonyls. This reaction is used, for instance, in the preparation of starting materials for the synthesis of pyranthrone and flavanthrone (see Section 2.12.7).

2-Methylanthraquinone [*84-54-8*], M_r 222.2, *mp* 182 – 183 °C, is prepared from phthalic anhydride and toluene (see also [1], [2, p. 10], [5, p. 40]).

2-Ethylanthraquinone [*84-51-5*], M_r 235.3, *mp* 108 °C, is prepared from phthalic anhydride and ethylbenzene [29].

2.3. Haloanthraquinones

Haloanthraquinones are important intermediates for all classes of dyes, especially for vat and disperse dyes.

Unsubstituted halogenated anthraquinones are prepared mainly by replacement reactions or by synthesis of the nucleus. Only the chloro derivatives are of practical importance. Aminoanthraquinones, hydroxyanthraquinones, phenoxyanthraquinones, and anthrimides (dianthraquinonylamines) may be obtained by replacing the chlorine atom. The β-chloroanthraquinones are much more suitable for preparing β-aminoanthraquinones than the corresponding sulfonic acids. In contrast to the 1,5- and the 1,8-dichloroanthraquinones, a single chlorine atom of 2,3-dichloroanthraquinone can be replaced by ammonia to give 2-amino-3-chloroanthraquinone in good yield [5, p. 30].

Haloanthraquinones with additional substituents commonly are prepared by direct halogenation of the corresponding anthraquinones in water, hydrochloric acid, sulfuric acid, or organic solvents. Electron-withdrawing substituents, such as sulfonic acid or nitro groups, direct the halogenation to the other nucleus.

Anthraquinones with electron-donating substituents, such as amino or hydroxy groups, permit selective halogenation of one or the other nucleus by appropriate choice of reaction conditions. Only the chloro and bromo derivatives are commercial products.

Process Details. Direct chlorination of anthraquinone with chlorine or sulfuryl chloride, occurs preferentially at the α position;

however, the resulting product mixtures are difficult to separate. Only 1,4,5,8-tetrachloroanthraquinone of about 60 % purity [30] and 1-chloro-2methylanthraquinone are prepared commercially by this method [2, p. 60].

Replacement of sulfonic acid groups by chlorine is called the Fischer reaction in honor of its discoverer, A. Fischer. Sulfonic acid groups in both the α and β position are replaced.

The reaction is carried out by slowly adding an aqueous solution of sodium chlorate to a hot hydrochloric acid solution of the anthraquinonesulfonic acid. The resulting, only slightly soluble chloroanthraquinones are isolated by filtration. The almost quantitative reaction is also used for the identification of anthraquinonesulfonic acids. The Fischer reaction of disulfonic acids can be directed in such a way that mostly monochloroanthraquinonesulfonic acids form.

A nitro group can be replaced by a chlorine atom at high temperature, generally above 200 °C, using chlorine or ionic chlorides, such as lithium chloride, in organic solvents [33]. A proposed industrial method is the reaction of chlorine with nitroanthraquinone in the melt [31]. Diluents for the high-melting nitroanthraquinones are lower melting compounds, such as chloroanthraquinone [32], trichlorobenzene [110], phthalic anhydride [42], and salt melts [34]. Chloroanthraquinones can be purified [35] and separated [36] by high-temperature distillation.

1,4-Dichloroanthraquinone may be obtained by replacing the hydroxy groups of 1,4-dihydroxyanthraquinone (quinizarin) with chlorine by heating with thionyl chloride [37] or with mixtures of phosphoryl chloride and phosphorus pentachloride [38].

The replacement of amino groups by chlorine through diazotization and treatment with cuprous chloride (Sandmeyer reaction) is used commercially only in special cases (see Section 2.5).

A few chloroanthraquinones can be obtained by synthesis of the nucleus via the corresponding benzoylbenzoic acids. Because β-anthraquinonesulfonic acids react slowly in the Fischer reaction, industrial production of 2-chloroanthraquinone starts generally from phthalic anhydride and chlorobenzene [2, pp. 8, 11].

1-Chloroanthraquinone [*82-44-0*], M_r 242.7, *mp* 162 °C, is prepared from anthraquinone-1-sulfonic acid [4, p. 29], [39], or from 1-nitroanthraquinone [31], [32]. Purification by high-temperature distillation [35], [36].

2-Chloroanthraquinone [*131-09-9*], M_r 242.7, *mp* 210 °C, is prepared by synthesis of the nucleus starting with phthalic anhydride and chlorobenzene [2, pp. 8, 11].

1,5-Dichloroanthraquinone [*82-46-2*], M_r 277.1, *mp* 251 °C, is prepared by Fischer reaction from anthraquinone-1,5-disulfonic acid, by addition of chlorobenzenes [40], or from 1,5-dinitroanthraquinone [32] by replacement of NO_2 .

1,8-Dichloroanthraquinone [*82-43-9*], M_r 277.1, *mp* 203 °C, is prepared from anthraquinone-1,8-disulfonic acid [3, p. 15] or from 1,8-dinitroanthraquinone [32].

1,4-Dichloroanthraquinone [*602-25-5*], M_r 277.1, *mp* 187 °C, is prepared from 1,4-dihydroxyanthraquinone [37], [38] or by synthesis of the nucleus from phthalide and 1,4-dichlorobenzene [41].

2,3-Dichloroanthraquinone [*84-45-7*], M_r 277.1, is prepared by synthesis of the nucleus from phthalic anhydride and 1,2-dichlorobenzene [2, p. 10].

1,4,5,8-Tetrachloroanthraquinone [*81-58-3*], M_r 346.0, *mp* 342 °C, is prepared by chlorination of anthraquinone in sulfuric acid [30] or by sulfonation of 1,8-dichloroanthraquinone followed by Fischer reaction [43].

1-Chloro-2-methylanthraquinone [*129-35-1*], M_r 256.7, *mp* 171 °C, is prepared from 2-methylanthraquinone by direct chlorination in oleum [2, p. 60] or organic solvents [44].

2-Chloro-3-methylanthraquinone [*14684-09-4*], M_r 256.7, is prepared by synthesis of the nucleus from phthalic anhydride and 2-chlorotoluene [45].

2.4. Nitroanthraquinones

Nitration of anthraquinones has considerable industrial importance. Examples of compounds that may be nitrated are anthraquinone and the halo-, hydroxy-, amino-, and acylaminoanthraquinones. As a rule the nitro group attacks at the α position; choice of reaction conditions frequently permits mono- or dinitration.

Prior to the discovery of α-sulfonation of anthraquinone, nitration was the only useful method for preparing α-substituted anthraquinones. The nitro group of α-nitroanthraquinones may be replaced in a manner similar to the sulfonic acid moiety, e.g., by chlorine atoms and amino, hydroxy, alkoxy, or mercapto groups. Reduction readily yields aminoanthraquinones. Nitration of anthraquinone has gained increasing importance because of environmental considerations, this method offering an economical alternative to α-sulfonation.

1-Nitro-2-methylanthraquinone is the starting material for 1-amino-4-bromo-2-methylanthraquinone, 1-aminoanthraquinone-2-aldehyde, and 1-aminoanthraquinone-2-carboxylic acid derivatives.

Process Details. Substituted anthraquinones usually are nitrated in concentrated sulfuric acid using stoichiometric quantities of nitric acid or nitric – sulfuric mixed acid. This method always produces considerable amounts of dinitro compound in addition to the mononitro compound. Even the best methodology permits preparation of only 75 – 80 % of the theoretical amount of 1-nitroanthraquinone. Mononitration in highly concentrated nitric acid also has been developed to an acceptable procedure by avoiding concentration levels that can lead to explosions [46–49]. Dinitration can be retarded significantly during nitration with mixed acids by increasing the water content [50–52]. Other procedures specify the presence of organic solvents, such as halogenated hydrocarbons [54], [55], [56], sulfolane (tetrahydrothiophene-1,1-dioxide) [57], hydrofluoric acid [58], or phosphoric acid [59]. Some of these methods can be adapted to continuous processing.

Mononitration of 2-methylanthraquinone leads to 2-methyl-1-nitroanthraquinone [2, p. 13]. Nitration of anthraquinone-1-sulfonic acid produces a mixture of 1-nitroanthraquinone-5-sulfonic acid and 1-nitroanthraquinone-8-sulfonic acid, whereas nitration of anthraquinone-2-sulfonic acid produces a mixture of 1-nitroanthraquinone-6-sulfonic acid and 1-nitroanthraquinone-7-sulfonic acid.

Halogen exchange by nitrite is an unimportant method of preparing nitroanthraquinones. There are only a few patents directed toward the synthesis of more highly substituted nitroanthraquinones, e.g., [82].

Finally, preparations of nitroanthraquinones by means of nuclear syntheses, for instance, by addition of butadiene to 5-nitronaphthoquinone (or its oxime), have also been proposed [83], [84].

Several methods have been developed to remove 2-nitroanthraquinone and dinitroanthraquinones from 1-nitroanthraquinone. The chemical purification processes are based on the treatment of the crude product with sodium sulfite

[60] or alkaline reagents, such as amines [61], alcoholates [62], or hydrazine [63], which cause preferential conversion of the contaminants to compounds that can be separated easily on the basis of their different solubilities. The more economical physical separation methods incorporate prepurification into the nitration process (e.g., crystallization from nitric acid [64]), or the isolated crude 1-nitroanthraquinone is purified with organic solvents, such as nitrobenzene [65] or amides [66]. Pure 1-nitroanthraquinone is then obtained by high-temperature distillation [67], [68].

Purification may also be deferred to the aminoanthraquinone stage (see page 13.

Modification of nitration conditions permits *dinitration* of anthraquinone. Nitration in highly concentrated nitric acid, as cited in [69], is for safety reasons unsuitable for industrial production [70]. However, addition of sulfuric acid makes it possible to work with a margin of safety [71]. The preferred method for dinitration is still the use of mixed nitric – sulfuric acid [72], [73]. However, nitration in organic solvents [74] or hydrofluoric acid [75] have been proposed also.

Apart from approximately equal portions of 1,5- and 1,8-dinitroanthraquinones, dinitration produces α,β-dinitroanthraquinone. The direct isolation of 1,5- and 1,8-dinitroanthraquinone is possible from the nitration mixtures [76] or, starting from isolated crude dinitroanthraquinone mixtures, by fractional crystallization from organic solvents, e.g., nitrobenzene [77], *N*-methylpyrrolidone [78], or high-boiling ketones [79]. Other procedures that simply separate the α,β-dinitroanthraquinones have been described also [80].

1-Nitroanthraquinone [*82-34-8*], M_r 253.2, *mp* 228 °C, is prepared by nitration of anthraquinone in nitric acid (danger of explosion!) [46–49], sulfuric acid [50–52], organic solvents [54–57], phosphoric acid [59], or hydrogen fluoride [58].

Purification from organic solvents by addition of bases, such as amines [61], alcoholates [62], or hydrazine [63], or from water by addition of sodium sulfite [60]. 1-Nitroanthraquinone is crystallized from nitric acid [64], from organic solvents, for example, nitrobenzene [65], or from amides [66]. The resulting 1-nitroanthraquinone may be finally purified by high-temperature distillation [67], [68].

1,5-Dinitro- and 1,8-dinitroanthraquinones [*82-35-9*], [*129-39-5*], M_r 298.2, are prepared by nitration of anthraquinone with nitric acid in sulfuric acid [72], [73], if necessary by addition of organic solvents [74], or in hydrogen fluoride [75].

For isolation and purification of mixtures of 1,5- (and 1,8-) dinitroanthraquinone, see [80]. Isolation of 1,5- (and 1,8-) dinitroanthraquinone is described in [77–79].

1-Nitroanthraquinone-5- (and -8-) sulfonic acids [*82-50-8*], [*129-37-3*], M_r 333.3, are prepared by nitration of anthraquinone-1-sulfonic acid [81].

2-Methyl-1-nitroanthraquinone [*129-15-7*], M_r 267.7, is prepared by nitration of 2-methylanthraquinone [2, p. 13].

2.5. Aminoanthraquinones

2.5.1. General Aspects

Aminoanthraquinones, especially 1-amino- and 1,5-diaminoanthraquinone, are key products for essentially all classes of anthraquinone dyes. Important production methods are the replacement of sulfonic acid and nitro groups or of halogen atoms by ammonia or primary or secondary amines. With 1,4-dihydroxy-, 1,4-aminohydroxy-, and 1,4-diaminoanthraquinones, the replacement of hydroxy and amino groups is also successful. Primary aminoanthraquinones are also prepared by reduction of nitroanthraquinones. Modifications of the amino functions also have industrial importance. These include alkylation, arylation, acylation, and hydrolysis of acylaminoanthraquinones. The choice of production method for a desired aminoanthraquinone depends on the position and type of the amino function, as well as on the availability of starting materials.

A special method for the production of 1-aminoanthraquinone consists in the catalytic hydrogenation of 5-nitro-1,4,4 a,9 a-tetrahydroanthraquinone, which is obtained by reacting butadiene and 5-nitronaphthoquinone (see [85]).

Aminoanthraquinones may be purified by recrystallization, distillation, or sublimation. However, purification is preferred at the stage of the nitroanthraquinones or the anthraquinonesulfonic acids.

In most situations the presence of the amino group facilitates the introduction of further substituents into the same ring. Reaction media and conditions as well as type and position of the amino group determine the position of substitution.

In addition to conversion of existing amino groups to other amino functions, the amino groups also may be replaced by halogen or hydroxy substituents through diazotization followed by the Sandmeyer reaction.

2.5.1.1. Replacement Reactions

$SO_3H \rightarrow NHR$ (R = H or alkyl). The replacement of sulfonic acid groups by amino or alkylamino groups can be carried out successfully with both unsubstituted and further substituted anthraquinonesulfonic acids. Depending on the choice of reaction conditions, diaminoanthraquinones and aminoanthraquinonesulfonic acids may be obtained from disulfonic acids. The α- and β-sulfonic acids react both with ammonia. In the reaction with alkylamines, only the α derivatives give commercially important products. Yields are determined in part by the number of sulfonic acid groups and in part by the type of amine and are on the order of 70 – 90 %.

The exchange reactions are carried out in aqueous medium at 120 – 200 °C and under pressure. To avoid attachment of displaced sulfite, an oxidizing agent, e.g., *m*-nitrobenzenesulfonic acid, is usually added.

Halogen $\rightarrow NH_2$ or NHR. Of great importance industrially is the replacement of chlorine and bromine atoms in the α or β positions by amines in substituted and unsubstituted haloanthraquinones. Reagents for this purpose are ammonia, aliphatic and aromatic amines, aminoanthraquinones, and amides, such as *p*-toluenesulfonamide or phthalimide. Because of the increased reactivity of the α positions, the halogen atoms at the α positions of α,β-dihaloanthraquinones may be reacted selectively.

The partial replacement of halogen in α,α- and β,β-*dihaloanthraquinones,* for example, in 2,3-dichloroanthraquinone, is also a known process.

Haloanthraquinones without sulfonic acid groups are reacted in the presence of excess amine or in such organic solvents as alcohol, halobenzene, nitrobenzene, naphthalene, or *N*-ethylcarbazole. Reaction temperatures range from 100 to 250 °C, and the reaction is carried out in the presence of acid-neutralizing agents. Alkali carbonates, acetates, and stearates are suitable for this purpose. The reaction is accelerated by the addition of copper catalysts. In many cases, for example, in the preparation of anthrimides, the copper catalyst is necessary.

Acylation of *1-amino-4-haloanthraquinones* may increase the reactivity of the halogen atom.

Haloanthraquinones with sulfonic acid groups generally are reacted with amines in water or water–alcohol mixtures at temperatures up to 100 °C in the presence of alkali carbonates, alkali hydrogen carbonates, acetates, or hydroxides. The addition of a copper catalyst is absolutely essential in these reactions. Its action is reputed to be enhanced by adding Fe(II) salts [86].

Of great industrial importance are the reactions of 1-amino-4-bromoanthraquinone-2-sulfonic acid (bromamine acid). Yields depend strongly on the choice of the reaction conditions and the reactivity of the amine. Strongly basic amines require the addition of alkali-metal hydroxides. Sterically hindered amines, such as 2,4,6-trimethylaniline, react very slowly.

Amines with very low basicity are unreactive or react slowly. A side reaction of the bromamine acid reaction is the reductive elimination of the halogen atom and formation of 1-aminoanthraquinone-2-sulfonic acid or the replacement by a hydroxy group to form 1-amino-4-hydroxyanthraquinone-2-sulfonic acid.

$NO_2 \rightarrow NH_2$ or NHR. Aminoanthraquinones with primary amino groups may be prepared by replacement reactions or, even more simply, by reduction of the corresponding nitroanthraquinones. The industrial reducing agents are usually sodium sulfide or sodium hydrogen sulfide [87]. Reduction also may be accomplished with sulfur dioxide in ≈ 60 % sulfuric acid in the presence of catalytic quantities of iodine [88]. Other methods, particularly for the preparation of 1-aminoanthraquinone, include reduction by hydrazine in aqueous sodium hydroxide [89], by metals such as iron in sulfuric acid [90], and by hydrogenation in organic solvents in the presence of palladium or Raney nickel [91]. If catalytic hydrogenation is carried out in dilute sodium hydroxide solution, a purification effect may take place if the 1-nitroanthraquinone is contaminated with dinitroanthraquinone. A stepwise reduction with purification at the hydroxylamino stage has been proposed also [92]. Highly purified 1-aminoanthraquinone is obtained by high-temperature distillation [68].

Replacement of nitro groups by amino groups using ammonia leads to good yields and high quality 1-aminoanthraquinone and 1,5-diaminoanthraquinone. The reaction commonly is carried out at 140 – 170 °C, optionally under pressure, in organic solvents, such as alcohols [93], amides [94], xylene [95], chlorobenzene [96], or tetramethylene sulfone [97]. The use of ammonium salts or urea in place of ammonia has also been proposed [94].

Replacement of nitro groups by alkylamines or arylamines is favored in the production of secondary amines. Replacement reactions with 1-aminoanthraquinone to form anthrimides are also successful [98].

When dinitroanthraquinones are used as starting materials, the choice of reaction conditions makes a partial exchange possible. The reaction is carried out in water or organic solvents, or in an excess of the amine.

$OH \rightarrow NH_2$ or NHR (R = H, alkyl, aryl). The replacement of the hydroxy group by the amino group is limited to 1,4-dihydroxy- and 1-amino-4-hydroxyanthraquinone. It occurs via the 2,3-dihydro compounds and is reversible.

R = H, Alkyl, Aryl

Exchange reactions are carried out using ammonia, aliphatic and aromatic amines, and mixtures of amines. The starting material is the isolated 2,3-dihydro compound, generally as a mixture with dihydroxyanthraquinone. Alterna-

tively, the intermediate may be prepared in-situ by addition of reducing agents such as zinc–hydrochloric acid or iron – acetic acid. The reaction media are water, alcohol, or excess amine. The primary product, 2,3-dihydro-1,4-diaminoanthraquinone, is oxidized to 1,4-diaminoanthraquinone either during the reaction mediated by dihydroxyanthraquinone or afterwards, by reaction with air. It is also possible to isolate the dihydro compound and then oxidize it with oleum, manganese dioxide – sulfuric acid, or nitrobenzene in the presence of piperidine.

In 1,4-dihydroxyanthraquinone, both hydroxy groups are replaced in an excess amine. In the presence of additional diluents, such as alcohols, generally only one hydroxy group is exchanged. As expected, sterically hindered amines are not very reactive.

$NH_2 \rightarrow NHR$. The amino groups of 1,4-diaminoanthraquinones may be replaced by other amino groups via the 2,3-dihydro compounds.

OR → NHR. Replacement of ether functions by amino groups occasionally offers advantages over the other methods, especially in reactions with reducing amines.

2.5.1.2. Modifications of the Amino Functions

$NH_2 \rightarrow NHR$ (R = alkyl). The preparation of alkylaminoanthraquinones by alkylation of aminoanthraquinones can be achieved by commonly employed methods, e.g., with dimethyl sulfate, alkyl halides, or esters of toluenesulfonic acid. A special process is the methylation with methanol in sulfuric acid [108]. When used on aminohydroxy- and diaminoanthraquinones this process gives mixed products of interest to dyers.

$NH_2 \rightarrow NHR$ (R = aryl). The preparation of simple arylanthraquinones by arylation of aminoanthraquinones with aromatic halides, such as chlorobenzenes or chloronaphthalenes, has no industrial importance. However, arylation is used for the preparation of dianthraquinonylamines and similar compounds, which are classified under the term *anthrimides,* e.g., dianthrimide, see page 14. In this case aminoanthraquinones are reacted with chloroanthraquinones or nitroanthraquinones. The reaction is carried out in high-boiling solvents, such as naphthalene or nitrobenzene, at temperatures of 150 – 250 °C. Certain cases do not require a solvent (so-called "baking process").

Acid-binding agents used in the preparation of anthrimides include alkali carbonates, acetates, oleates, stearates, and alkaline-earth oxides. Catalysts in the reactions of haloanthraquinones are copper and copper salts. Nitroanthraquinones also may be reacted without a catalyst. Anthrimides may be isolated by filtration or distilling the solvent away. Inorganic salts are removed by boiling with water or dilute mineral acids.

A special reaction for the preparation of anthrimides is the oxidation of aminoanthraquinones in aqueous sulfuric acid: 1-aminoanthraquinone yields aminopolyanthrimides [99]. Mixtures of 1-aminoanthraquinone and 1,4-diaminoanthraquinone yield diaminodianthrimide [100].

Various anthrimides are suitable as vat dyes, but they find their main use in the preparation of anthrimidecarbazoles (see Section 2.11.2).

$NH_2 \rightarrow NH$ – Heteroaryl. Of importance here are mostly the triazinylaminoanthraquinones, where R^1 and/or R^2 may constitute anthraquinonylamino residues.

Due to the high reactivity of chlorotriazines, one does not require a catalyst or, acid-binding agents. In addition to high boiling organic solvents such as nitrobenzene, phenols have proved valuable in the preparation of trisanthraquinonylaminotriazines [101].

The reaction may be accelerated by adding tertiary amines, and in special cases by adding catalytic quantities of a Lewis acid such as $AlCl_3$ or $FeCl_3$.

$NH_2 \rightarrow$ NH-CO-R. The most important method of preparing acylaminoanthraquinones is the acylation of aminoanthraquinones with acid chlorides, preferably in an organic solvent, such as nitrobenzene or dichlorobenzene. A further method is the reaction of aminoanthraquinones with carboxylic acids or their anhydrides in oleum. Depending on the position of the amino groups and the nature of the acid chloride, diaminoanthraquinones also may be acylated in one position only, giving 60 – 90 % yields:

NHR $\rightarrow NH_2$. Secondary or tertiary alkyl aminoanthraquinones are converted into aminoanthraquinones by removal of the alkyl residue under the influence of acid or alkaline agents. This method is also applicable to cycloalkyl- [102] and aralkylaminoanthraquinones and facilitates the preparation of certain aminoanthraquinones that are accessible only with difficulty. In the reaction of sterically hindered arylamines with 1-amino-4-bromoanthraquinone-2-sulfonic acid (bromamine acid), this cleavage occurs as an undesirable side reaction, forming 1,4-diaminoanthraquinone-2-sulfonic acid.

NH-CO-R and NH-SO_2-R $\rightarrow NH_2$. Acylaminoanthraquinones are hydrolyzed in dilute to concentrated sulfuric acid as well as in 2 – 10 % aqueous sodium hydroxide at temperatures ranging from 20 to 150 °C. The sulfonamides are more stable in alkaline medium than in an acidic medium. They are especially easily cleaved in concentrated sulfuric acid. Because arylsulfonylaminoanthraquinones are smoothly prepared from haloanthraquinones (see page 19), this method is suitable for the production of aminoanthraquinones otherwise difficult to prepare. Hydrolysis of arylamino groups depends also on additional substituents. For instance, alkaline hydrolysis of 1,5-bis(benzoylamino)-4-hydroxyanthraquinone causes hydrolysis of the 5-benzoylamino group, whereas acidic medium causes cleavage of the 1-benzoylamino group.

2.5.1.3. Substitutions on the Aminoanthraquinone Nucleus

Nucleus H $\rightarrow SO_3H$. 1-Aminoanthraquinone- 2-sulfonic acids are prepared by sulfonation of aminoanthraquinones in oleum or chlorosulfonic acid. In order to suppress the sulfonation and oxidation of the 4 position as much as possible, chlorosulfonic acid in organic solvents or, alternatively, oleum in the presence of sodium sulfate is used. When 1,4-diaminoanthraquinone is sulfonated in oleum, addition of boric acid (to form cyclic boric acid amides) directs the sulfonic acid group into the 6 position. Sulfonation of β-aminoanthraquinones has no commercial importance.

An alternative method for the introduction of sulfonic acid groups consists of the treatment of α-aminoanthraquinone with aqueous alkali-metal sulfites.

Nucleus H $\rightarrow$ Halogen. Aminoanthraquinones may be halogenated with the usual halogenation agents such as chlorine, bromine, and sulfuryl chloride. Suggested reaction media

are hydrochloric acid, oleum, glacial acetic acid, sodium chloride–aluminum chloride melts, and inert solvents, such as chlorobenzene, nitrobenzene, halogenated hydrocarbons, and amides. The reaction of 1-aminoanthraquinone with chlorine or sulfuryl chloride [1] in inert solvents such as nitrobenzene leads to 1-amino-2,4-dichloroanthraquinone, whereas addition of tetraalkylureas [103] leads to 1-amino-2,3,4-trichloroanthraquinone. However, if 1-amino- or 1-phthalimidoanthraquinone is chlorinated in oleum, a good yield of 1-amino-5,8-dichloroanthraquinones is obtained, if necessary after hydrolysis of intermediates:

Use of 1-benzoylaminoanthraquinone as the starting material generally leads to substitution at the 4 position. Hydrolysis then yields the 1-amino-4-chloroanthraquinone. This compound may be obtained in better yields by chlorination of 1-formamidinoanthraquinone in oleum followed by hydrolytic cleavage of the protective group.

Bromination of 1-aminoanthraquinone in hydrochloric acid yields 1-amino-2,4-dibromoanthraquinone.

Chlorination of 1,4-diaminoanthraquinone in organic solvents with chlorine or sulfuryl chloride yields 1,4-diamino-2,3-dichloroanthraquinone; in boric acid–oleum, the 5,8-dichloro derivative is formed. In hydrochloric acid, 1-amino-2-methylanthraquinone and 1-aminoanthraquinone-2-sulfonic acid are brominated at the 4 position.

The 1-alkylaminoanthraquinones behave differently from the 1-aminoanthraquinones upon bromination in hydrochloric acid. In this case no substitution occurs at the 2 position, but the 1-alkylamino-4-bromoanthraquinones are formed in more than 90 % yield. By contrast, chlorination of 1-methylaminoanthraquinone in weak oleum [104] will give, in a manner similar to that of 1-aminoanthraquinone, the 5,8-dichloro-1-methylamino compound.

Nucleus $H \rightarrow CH_3$. Starting from 1-aminoanthraquinones, reaction with formaldehyde yields 1-amino-2-methylanthraquinones. The reaction proceeds in aqueous alkaline solutions via the leuco form of the aminoanthraquinone [115].

Nucleus $H \rightarrow NO_2$. In the nitration of aminoanthraquinones, which usually is carried out in sulfuric acid, the amino group must be protected by acylation or by formation of cyclic sulfimides. Location and number of the inserted nitro groups are determined to some extent by the nature of the protective group. For example, 1-ethoxycarbonylaminoanthraquinone yields the 1-amino-2,4-dinitroanthraquinone, whereas 1-phthalimidoanthraquinone yields the 4,5- (or 4,8-) dinitro derivatives [105]. If 1,4-diaminoanthraquinone is used as the starting material, 1,4-diamino-2-nitroanthraquinone is formed via the intermediate 1,4-bis(benzoylamino)anthraquinone. The nitro group enters the 5 position if the intermediate is the cyclic disulfimide **1**.

The dioxamic acid (**2**) of the 1,5-diaminoanthraquinone yields 1,5-diamino-4,8-dinitroanthraquinone after nitration and hydrolysis [106].

$SO_3H \rightarrow H$. In certain 4-substituted 1-aminoanthraquinone-2-sulfonic acids, replacement of the sulfonic acid by hydrogen is feasible by using reducing agents in aqueous alkaline medium. Sodium dithionite and glucose have been applied successfully here. This procedure is used in the preparation of 1-alkylamino- (or 1-arylamino-) 4-aminoanthraquinone:

The procedure has certain advantages for the preparation of 1,4-diaminoanthraquinones with sensitive amino residues. An electrochemical reductive desulfonation of β-anthraquinonesulfonic acids has been proposed also [107].

2.5.2. Individual Aminoanthraquinones

1-Aminoanthraquinone [*82-45-1*], M_r 223.2, *mp* 252 – 253 °C, is prepared from anthraquinone-1-sulfonic acid in aqueous ammonia by replacement of SO_3H (see page 8), [5, p. 22], from 1-nitroanthraquinone in organic solvents by replacement of NO_2 by ammonia (see page 9), [93–97]; by reduction of 1-nitroanthraquinone with sodium sulfide in water [87] or in organic solvents [109], with hydrazine hydrate [89], with metal powders [90], or by catalytic hydrogenation. This last reaction can be carried out in organic solvents [91], in sodium hydroxide solution [92], or in dilute sulfuric acid [111]. Purification is carried out by recrystallization from organic solvents [112], [113] or sulfuric acid [114]. The greatest purity is obtained by distillation [68].

2-Aminoanthraquinone [*117-79-3*], M_r 223.2, *mp* 302 – 303 °C. Older methods used anthraquinone-2-sulfonic acid as the starting material, replacing the SO_3H group. The preferred method is replacement of the chlorine in 2-chloroanthraquinone (see page 8), [2, p. 20].

1-Amino-2-methylanthraquinone [*82-28-0*], M_r 237.3, *mp* 202 °C, is prepared by nitration of 2-methylanthraquinone [2, p. 13] followed by reduction or by methylation of 1-aminoanthraquinone with formaldehyde [115].

1,2-Diaminoanthraquinone [*1758-68-5*], M_r 238.2, *mp* 303 – 304 °C, is prepared from 1-aminoanthraquinone-2-sulfonic acid by SO_3H exchange (see page 8, [5, p. 98].

1,4-Diaminoanthraquinone [*128-95-0*], M_r 238.2, *mp* 268 °C, is prepared by hydroxyl replacement from 1,4-dihydroxyanthraquinone via the 2,3-dihydro compound and subsequent oxidation of the intermediate 2,3-dihydro-1,4-diaminoanthraquinone [5, p. 51].

1,5-Diaminoanthraquinone [*129-44-2*], M_r 238.2, *mp* 319 °C, is prepared by SO_3H exchange from anthraquinone-1,5-disulfonic acid (see page 8), [3, p. 14], [5, p. 43], by replacing NO_2 in 1,5-dinitroanthraquinone (see page 9), [116], or by reducing 1,5-dinitroanthraquinone with sodium sulfide or by catalytic hydrogenation [117].

1,8-Diaminoanthraquinone [*129-42-0*], M_r 238.2, *mp* 262 °C, is prepared by the methods given for 1,5-diaminoanthraquinone.

1,4,5,8-Tetraaminoanthraquinone [*2475-45-8*], M_r 268.3, *mp* 332 °C, is prepared from anthraquinone-1,5-dioxamic acid by nitration, hydrolysis, and reduction [3, p. 53].

1-Methylaminoanthraquinone [*82-38-2*], M_r 237.3, *mp* 170 °C, is prepared from anthraquinone-1-sulfonic acid by replacing SO_3H (see page 8), [3, p. 18], from 1-chloroanthraquinone by replacing chlorine (see page 8), [118], or from 1-nitroanthraquinone by replacing NO_2 (see page 9) [119], [120].

1-Isopropylaminoanthraquinone [*27354-18-3*], M_r 265.3, *mp* 187 °C, is prepared by replacement of SO_3H [121] or NO_2 [120], [121].

1,4-Bis(methylamino)anthraquinone [*2475–44–7*], M_r 266.3, is prepared by replacement of the hydroxy groups from 1,4-dihydroxyanthraquinone (see page 9) via the 2,3-dihydro compound [122].

1-Methylamino-4-(3-dimethylaminopropylamino)anthraquinone, (**3**), M_r 337.4, is prepared from 4-bromo-1-methylaminoanthraquinone (see page 8), [123].

3 4

1-Methylamino-4-(2-hydroxyethylamino)anthraquinone [*2475-46-9*], (**4**), M_r 296.3, is prepared (in admixture with symmetrical and half-reacted exchange products) by replacement of NH_2 from 2,3-dihydro-1,4-diaminoanthraquinone with a mixture of methylamine and ethanolamine [124].

1-Amino-4-methylaminoanthraquinone [*1220–94–6*], M_r 252.2, is prepared from 1,4-diaminoanthraquinone by partial methylation [125], from 1-amino-4-methylaminoanthraquinone-2-sulfonic acid by reductive SO_3H cleavage (see page 12), [126], from 2,3-dihydro-1,4-dihydroxyanthraquinone by hydroxyl replacement (see page 9) [122], or from 2,3-dihydro-1,4-diaminoanthraquinone by replacement of NH_2 [127] (in admixture with 1,4-bismethylaminoanthraquinone).

1-Cyclohexylaminoanthraquinone [*1096-48-6*], M_r 305.4, is prepared by replacing SO_3H, chlorine, or NO_2 [119].

1,5-Bis-(2-nitrophenylamino)anthraquinone [*21982-51-4*], (**5**), M_r 480.4, is prepared from 1,5-diaminoanthraquinone and 2-chloronitrobenzene [128].

5

1-Benzoylaminoanthraquinone [*3571-23-1*], M_r 327.3, *mp* 248 – 249 °C, is prepared from 1-aminoanthraquinone and benzoyl chloride [129] or from 1-chloroanthraquinone and benzamide [130].

1,4-Bis-(benzoylamino)anthraquinone [*2987-68-0*], Indanthren Red 5 GK, M_r 446.4, is prepared from 1,4-diaminoanthraquinone and benzoyl chloride [4, p. 40].

1,5-Bis(benzoylamino)anthraquinone [*82-18-8*], Indanthren Yellow GK, M_r 446.4, *mp* 350 °C, is prepared from 1,5-diaminoanthraquinone with benzoyl chloride [131] or from 1,5-dichloroanthraquinone with benzamide [130], [132].

1-Amino-4-benzoylaminoanthraquinone [*81-46-9*], M_r 342.3, is prepared from 1,4-diaminoanthraquinone with benzoyl chloride [3, p. 4].

1-Amino-5-benzoylaminoanthraquinone [*117-06-6*], M_r 342.3, *mp* 244 – 245 °C, is prepared from 1,5-diaminoanthraquinone with benzoyl chloride [3, p. 4] or from 1-chloro-5-benzoylaminoanthraquinone with arylsulfamides and subsequent hydrolysis [133].

1,1′-Dianthraquinonylamine [*82-22-4*], dianthrimide, (**6**), M_r 429.4, is prepared by reacting 1-aminoanthraquinone with 1-chloroanthraquinone in nitrobenzene [4, p. 29] or water [134]. Also from 1-aminoanthraquinone and 1-nitroanthraquinone [98].

6

7

4,4′-Diamino-1,1′-dianthraquinonylamine [*128-87-0*], (**7**), M_r 459.4, is prepared by nitration of dianthrimide followed by reduction [4, p. 30], [5, p. 138] or by oxidation of a mixture of 1-aminoanthraquinone and 1,4-diaminoanthraquinone in aqueous sulfuric acid [100].

4,4′-Bis(benzoylamino)–1,1′-dianthraquinonylamine [*128-79-0*], (**8**), M_r 667.7, is prepared from 4,4′-diamino-1,1′-dianthrimide with benzoyl chloride [4, p. 31], [5, p. 139].

8

9

1,4-Bis-(1-anthraquinonylamino)anthraquinone [*116-76-7*], 1,1′,4′,1″-trianthrimide, (**9**), M_r 650.7, is prepared from 1 mol of 1,4-diaminoanthraquinone and 2 mol of 1-chloroanthraquinone [5, p. 102], [134].

***N,N′*-Bis-(1-anthraquinonyl)isophthalamide** [*3627-47-2*], Indanthren Yellow 5 GK, (**10**), M_r 576.6, is prepared from 1-aminoanthraquinone and isophthaloyl chloride [12, p. 596].

10

1-Amino-4-chloroanthraquinone [*2872-47-1*], M_r 257.7, *mp* 179 – 180 °C, is prepared by chlorination of 1-benzoylaminoanthraquinone with sulfuryl chloride [135] and subsequent hydrolysis or by chlorination of anthraquinonyl-1-formamidinium salt followed by hydrolysis [136].

2-Amino-3-chloroanthraquinone [*84-46-8*], M_r 257.7, *mp* 280 – 283 °C, is prepared from 2,3-dichloroanthraquinone by chlorine replacement (see page 8) [5, p. 30].

1-Amino-4-chloro-2-methylanthraquinone [*3225-97-6*], M_r 271.7, *mp* 255 – 256 °C, is prepared from 1-amino-2-methylanthraquinone by chlorination with sulfuryl chloride [137] or chlorine [138].

1-Benzoylamino-4-chloroanthraquinone [*81-45-8*], M_r 361.8, is prepared from 1-aminoanthraquinone by benzoylation in nitrobenzene [3, p. 13] and subsequent chlorination with sulfuryl chloride.

1-Benzoylamino-5-chloroanthraquinone [*117-05-5*], M_r 361.8, is prepared from 1-amino-5-benzoylaminoanthraquinone by diazotization and Sandmeyer reaction with Cu_2Cl_2 or by benzoylation of 1-amino-5-chloroanthraquinone in *o*-dichlorobenzene using benzoyl chloride [4, p. 16].

1-Amino-2,4-dichloroanthraquinone [*13432-32-1*], M_r 292.1, *mp* 217 – 219 °C, is prepared by chlorination of 1-aminoanthraquinone in nitrobenzene [139].

1-Amino-5,8-dichloroanthraquinone [*3223-94-7*], M_r 292.1, *mp* 199 °C, is prepared by chlorination of 1-aminoanthraquinone in chlorosulfonic acid or in oleum with a low percentage of SO_3 [140].

1,4-Diamino-2,3-dichloroanthraquinone [*81-42-5*], M_r 307.1, is prepared by chlorination of 1,4-diaminoanthraquinone or leuco-1,4-diaminoanthraquinone [4, p. 18] with sulfuryl chloride.

1-Amino-2,4-dibromoanthraquinone [*81-49-2*], M_r 381.0, *mp* 221 °C, is prepared from 1-aminoanthraquinone by bromination in dilute mineral acids [3, p. 6].

4-Bromo-1-methylaminoanthraquinone [*128-93-8*], M_r 316.1, *mp* 194 °C, is prepared from 1-methylaminoanthraquinone by bromination [141].

4-Bromo-1-isopropylaminoanthraquinone [*23573-29-7*], M_r 344.2, is prepared from 1-isopropylaminoanthraquinone by bromination [141].

4-Bromo-1-cyclohexylaminoanthraquinone [*14233-28-4*], M_r 384.4, is prepared from 1-cyclohexylaminoanthraquinone by bromination [141].

1-Amino-2-bromo-4-(dimethylaminopropylamino)anthraquinone [*51818-35-0*], (**11**), M_r 402.3, is prepared from 1-amino-2,4-dibromoanthraquinone and dimethylaminopropylamine by bromine exchange [142].

11

1,4-Diamino-2-nitroanthraquinone, M_r 283.2, is prepared from 1,4-bis(benzoylamino)anthraquinone by nitration in a solvent and subsequent hydrolysis [143].

1,4-Diamino-5-nitroanthraquinone [*82-33-7*], M_r 283.2, is prepared from 1,4-diaminoanthraquinone via the cyclic disulfimide (the structure is shown in page 12), which is nitrated in sulfuric acid and then hydrolyzed [3, p. 20].

1,5-Diamino-4,8-dinitroanthraquinone [*10262-79-0*], M_r 328.3, is prepared from anthraquinone-1,5-bis-oxamidic acid by nitration and hydrolysis [106] or from anthraquinone-1,5-bis(formamidinium chloride) by nitration and hydrolysis in dilute sulfuric acid [144].

1,4-Diamino-2-bromo-5-nitroanthraquinone, M_r 362.1, is prepared from 1-amino-2,4-dibromo-5-nitroanthraquinone and *p*-toluenesulfonamide followed by hydrolysis [145].

1-Aminoanthraquinone-2-sulfonic acid [*83-62-5*], M_r 303.3, is prepared from 1-aminoanthraquinone by sulfonation with $ClSO_3H$ in an organic solvent (if nitrobenzene, danger of explosion) [5, p. 214], [146], [147], [149], or with oleum in the presence of Na_2SO_4 [148].

1-Amino-4-bromoanthraquinone-2-sulfonic acid [*116-81-4*], bromamine acid, (**12**), M_r 382.2, is prepared from 1-aminoanthraquinone-2-sulfonic acid by bromination in water [5, p. 214], [151] or in dilute acid [149], [150]. Alternatively, it can be prepared by a one-pot process: sulfonation and bromination in sulfuric acid without isolation of intermediates [152].

12

1,4-Diaminoanthraquinone-6-sulfonic acid [*64910-84-5*], M_r 318.3, is prepared by sulfonation of 1,4-diaminoanthraquinone in oleum in the presence of boric acid.

1-Aminoanthraquinone-2,5- (or -2,8-) disulfonic acid [*58294-46-5*], M_r 383.4, is prepared from 1-aminoanthraquinone-5- (or -8-) sulfonic acid by sulfonation [145], or from 1-cyclohexylaminoanthraquinone-5-sulfonic acid in oleum [102].

1-Aminoanthraquinone-2,6- (or -2,7-) disulfonic acid, M_r 383.4, is prepared from 1-nitroanthraquinone-6- (or -7-) sulfonic acid and Na_2S by formation of 1-amino-2-mercaptoanthraquinone-6- (or -7-) sulfonic acid followed by oxidation [153].

1-Isopropylaminoanthraquinone-5-sulfonic acid [*33175-83-6*], M_r 345.4, is prepared from anthraquinone-1,5-disulfonic acid by replacement of one SO_3H [154].

1-Cyclohexylaminoanthraquinone-5-sulfonic acid [*33175-82-5*], M_r 385.4, is prepared from anthraquinone-1,5-disulfonic acid by replacement of one SO_3H [155].

1,4-Bis-(*p*-toluidino)anthraquinone-2′,2″-disulfonic acid [*3443-90-1*], (**13**), M_r 578.6, is prepared from 1,4-dihydroxyanthraquinone and *p*-toluidine by replacement of hydroxyl followed by sulfonation [5, p. 215].

13

14

15

1,4-Bis-(2,6-dimethylanilino)anthraquinone-x′,x″-disulfonic acid, (**14**), M_r 606.7, is prepared from 1,4-dihydroxyanthraquinone and 2,6-dimethylaniline followed by sulfonation [156].

1,5-Bis-(*p*-toluidino)anthraquinone-2′,2″-disulfonic acid [*117-04-4*], (**15**), M_r 578.6, is prepared by replacement of NO_2 [157] or Cl [158] followed by sulfonation [159].

1,8-Bis-(*p*-toluidino)anthraquinone-2′,2″-disulfonic acid, (**16**), M_r 578.6, is prepared by replacement of NO_2 [157] or Cl followed by sulfonation [159].

16

17

1-Amino-4-anilinoanthraquinone-2-sulfonic acid [*2786-71-2*], (**17**), M_r 394.4, is prepared from bromamine acid and aniline [3, p. 41]. Compound **17** is a blue acid dye (e.g., Alizarine Saphirol A).

1-Amino-4-(*p*-methylaminomethylanilino)anthraquinone-2-sulfonic acid [*64135-01-9*], (**18**), M_r 437.5, is prepared from bromamine acid and *N*-(4-amino-benzyl) methylamine [160].

18

19

1-Amino-4-(2,4-diethyl-6-methylphenylamino)anthraquinone-2-sulfonic acid [*20074-70-8*], (**19**), M_r 464.5, is prepared from bromamine acid and 2,4-diethyl-6-methylaniline [161].

1-Amino-4-(4′-acetylaminoanilino)anthraquinone-2-sulfonic acid, a blue acid dye, (**20**), M_r 451.1, is prepared from bromamine acid and 4-acetylaminoaniline [2, p. 135].

20

1-Amino-4-cyclohexylaminoanthraquinone-2-sulfonic acid [*5617-28-7*], is a brilliant blue acid dye (e.g., Alizarin Brilliant Pure Blue R), (**21**), M_r 400.5; it is prepared from bromamine acid and cyclohexylamine in the presence of NaOH [3, p. 30].

21

4-Bromo-1-isopropylaminoanthraquinone-5-sulfonic acid, (**22**), M_r 424.3, is prepared by bromination [397].

1-Amino-2-bromo-4-(4′-methylphenylsulfonamido)anthraquinone [*26868-32-6*], (**23**), M_r 471.3, is prepared from 1-amino-2,4-dibromoanthraquinone and *p*-toluenesulfonamide [162].

2.5.3. Diazotization of Aminoanthraquinones

Aminoanthraquinones may be diazotized by the usual methods in sulfuric acid. On an industrial scale, the diazotization of an aminoanthraquinone is accomplished by the conversion of 1-amino-5-benzoylaminoanthraquinone into 1-chloro-5-benzoylaminoanthraquinone by diazotization followed by the Sandmeyer reaction.

Azo derivatives of anthraquinone, which may be obtained by coupling diazotized aminoanthraquinones, are cited as colorants for a variety of applications [163]. Among the *hydrazino derivatives* only anthraquinone-1-hydrazinosulfonic acid is worth mentioning because it is obtained as an intermediate in the synthesis of pyrazoloanthrone (see Section 2.12.2).

2.6. Hydroxyanthraquinones, Alkoxy- and Aryloxyanthraquinones

Hydroxyanthraquinones are prepared primarily by synthesis of the nucleus, by exchange reactions, and by ether cleavage of alkoxy- (or aryloxy-) anthraquinones. The most important example of nucleus synthesis is the industrial production of 1,4-dihydroxyanthraquinone (quinizarin). Examples for exchange reactions are the conversion of anthraquinone-α,α'-disulfonic acids into α,α'-dihydroxyanthraquinones and the direct hydrolysis of a halogen in the 4 position in 1-amino-2,4-dihaloanthraquinone using boric–sulfuric acid. As the direct replacement of the nitro group by a hydroxy group frequently leads to side reactions, nitroanthraquinones are converted to hydroxyanthraquinones most readily via the corresponding alkyl or aryl ethers. In some cases, under rather special reaction conditions, direct replacement of one or more nitro groups is also possible. Replacement of halogen by hydroxy groups in otherwise unsubstituted haloanthraquinones is best carried out via the corresponding anthraquinone ethers. In individual cases the hydroxy groups also may be inserted at defined positions by oxidation.

Amino groups in 1,4-diamino- (or aminohydroxy-) anthraquinones are converted readily into hydroxy groups by reduction in alkaline medium via the 2,3-dihydro compounds or in an acid medium by oxidation via the quinoneimines.

Halogenation, nitration, and sulfonation of hydroxyanthraquinones present no special difficulties. Modification of the hydroxy group (boric acid esters, ethers) alters the mode of substitution. Derivatives of the hydroxy groups frequently enable a different or more selective substitution than the free hydroxy compounds.

2.6.1. General Aspects

2.6.1.1. Synthesis of the Nucleus

The preparation of quinizarin from phthalic anhydride and *p*-chlorophenol in boric–sulfuric acid has considerable industrial importance. The boric acid removes the quinizarin formed by formation of a stable boric acid ester which changes the equilibrium and, thus, enables the complete replacement of chlorine atoms by the hydroxy group.

Other methods, such as condensation of maleic anhydride with naphthohydroquinone [164] and the reaction of phthalic anhydride

with hydroquinone in molten aluminum chloride/sodium chloride, have not yet reached any level of importance.

2.6.1.2. Replacement Reactions

H → OH. Hydroxy groups may be introduced into anthraquinones in acid or alkaline media. Suitable oxidizing agents are manganese dioxide, potassium peroxodisulfate, potassium chlorate, or sodium nitrite. Whereas the synthesis of 1,2-dihydroxyanthraquinone (alizarine) by oxidation of anthraquinone requires an alkaline medium, preparation of 1,2,4-trihydroxyanthraquinone (purpurin) from 1,2- or 1,4-dihydroxyanthraquinone is carried out in sulfuric acid solution by oxidation with manganese dioxide. If 1,8-dihydroxyanthraquinone is oxidized with oleum containing a high percentage of SO_3 in the presence of boric acid, oxidation occurs in the 4 position to form 1,4,5-trihydroxyanthraquinone.

SO_3H → OR (R = H, alkyl). Hydroxy and alkoxy groups may be introduced by reactions similar to those employed for amino group displacement of sulfonic acid groups. For example, anthraquinone-α-sulfonic acids are converted by heating the anthraquinonesulfonic acid with an aqueous suspension of calcium hydroxide and magnesium chloride under pressure at 200–250 °C, to form α-hydroxyanthraquinones, e.g.,

However, sulfonic acid groups in the β position react only in an alkali melt at temperatures of 150–200 °C. If oxidizing agents are added, the α position is also hydroxylated, e.g., synthesis of alizarine from anthraquinone-2-sulfonic acid:

Further, anthraquinonesulfonic acids may be converted into alkoxyanthraquinones by alcoholic alkali at 50–120 °C. If higher temperatures are used, hydroxyanthraquinones are formed also. Anthraquinone aryl ethers are not prepared readily by this method. Instead, they are made from haloanthraquinones.

Halogen → OR (R = H, alkyl, aryl). Apart from the synthesis of quinizarin, direct replacement of halogen by hydroxy groups is of industrial importance only for replacing halogen in 1-amino-4-haloanthraquinones, e.g., **24** → **25** in the presence of boric–sulfuric acid. In all other cases, the haloanthraquinones are first converted with alcoholate or phenolate into the corresponding alkoxy- or phenoxyanthraquinones. This procedure is suitable for replacing halogens in both the α and the β position. However, for the preparation of β-alkoxyanthraquinones, it is recommended to generate first the β-phenoxy compound and then to subject this compound to an ether exchange reaction, e.g., **25** → **26** → **27**.

The corresponding hydroxy compounds are then accessible by acid hydrolysis of the alkoxy derivatives or by alkaline hydrolysis of the nitrated phenoxy derivatives.

NO_2 → OR (R=H, alkyl, aryl). Similar to halogen atoms, the nitro group may be replaced by hydroxy groups and ether residues. However, because direct replacement of hydroxy groups causes side reactions, only the reactions with alcoholate or phenolate, leading to the corresponding anthraquinone ethers, are of industrial importance. Alkoxyanthraquinones can then be converted to the hydroxyanthraquinones by acid cleavage.

These methods are important, especially for the preparation of 1,5- and 1,8-dialkoxy-, diphenoxy-, and dihydroxyanthraquinones, because industrial synthesis of anthraquinone intermediates is shifting more and more to the

use of nitroanthraquinones. In several cases, it is recommended that a sequence of reactions be done on the dialkoxyanthraquinones and the ether scission be performed at a later stage. In the case of 1,5-dihydroxy-4,8-dinitroanthraquinone, the replacement of one nitro group with boric–sulfuric acid presents no special difficulties, whereas the same method fails in the isomeric 1,8 compound.

NHR → OR (R=H, alkyl, aryl). The conversion of aminoanthraquinones to hydroxyanthraquinones is of little importance. Usual methods may be used to convert the amino group to the hydroxy group by means of diazotization and boiling of the reaction mixture.

The oxidative and the reductive degradation of 1,4-diamino- (or 1-amino-4-hydroxy)anthraquinones to the corresponding 1,4-dihydroxyanthraquinones is used to elucidate the structure of certain anthraquinone dyes. The reductive alkaline degradation, e.g., by treatment with warm sodium dithionite–sodium hydroxide, is used industrially for the manufacture of leuco-1,4,5,8-tetrahydroxyanthraquinone from 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulfonic acid:

2.6.1.3. Conversions of the Hydroxy Group

OH → Alkoxy, Alkoxy → OH. The *O*-alkylation of hydroxyanthraquinone may be carried out in the presence of acid-neutralizing agents using dimethyl sulfate or esters of *p*-toluenesulfonic acid. In the reverse reaction, anthraquinone alkyl ethers may be hydrolyzed with mineral acids to give hydroxyanthraquinones [165].

2.6.1.4. Substitutions on the Hydroxyanthraquinone Nucleus

Nucleus H → Alkyl, Aryl. α-Hydroxyanthraquinones react with aldehydes in aqueous alkaline sodium dithionite solutions, thereby alkylating the β position. Reaction of benzaldehyde with quinizarin, after conversion into the leuco form, yields 2-benzyl-1,4-dihydroxyanthraquinone [166], [167]:

Furthermore, hydroxyanthraquinones are capable of undergoing the Mannich reaction. Quinizarin, formaldehyde, and piperidine react, for instance, under formation of 1,4-dihydroxy-2-(piperidinomethyl)anthraquinone [168]:

When the hydrogen atoms in the β position are activated sufficiently, direct arylation of 1,4-substituted anthraquinones is also possible. This reaction is important in preparing arylated diaminodihydroxyanthraquinones, which can be accomplished by three methods: Addition to anthraquinonediquinone, aminohydroxyanthraquinone sulfonic acids, or hydroxynitroanthraquinones.

Generally applicable is the arylation of diquinones and diquinoneimines of 1,4,5,8-aminohydroxyanthraquinones:

28

Special methods are available for preparing arylated 4,8-diamino-1,5-dihydroxyanthraquinones, e.g., **28**, where the starting materials 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulfonic acid (**29**) or 4,8-dinitro-1,5-dihydroxyanthraquinone (**30**) determine the position of the substituent [169]. Both reactions are carried out at low temperature in boric–sulfuric

acid. This requires that in the following step the sulfonic acid groups be cleaved [170] or the remaining nitro groups be reduced [171]:

Nucleus H → SO_3H. Hydroxyanthraquinones are sulfonated in oleum. When the 1,4-dihydroxyanthraquinone is used as the starting material, addition of boric acid blocks sulfonation of the 2 position, and instead the sulfonic acid group enters the 5 or 6 position [3], [172]. In 1,5- (or 1,8-) dihydroxyanthraquinones, addition of sodium sulfate to the oleum may prevent an excessive sulfonation and the oxidation to higher hydroxylated products.

Nucleus H → Halogen. In general the choice of the halogenating agent has no influence on the substitution. Bromination is often preferred because of the greater ease in replacing bromine.

As hydroxy and amino groups generally enhance the reactivity towards halogenation, boric acid esters and boric ester amides of the 1,4-dihydroxy- (or hydroxyamino-) anthraquinones have a special function because they prevent substitution in the 2 and 3 positions. For example, quinizarin is halogenated in the 2 position in nitrobenzene and in the 5,8 positions in boric–sulfuric acid. The amino group has an additional effect on halogenation of aminohydroxyanthraquinones because halogenation is directed by either the hydroxy or the amino group, depending on the acidity of the medium. 1-Amino-4-hydroxyanthraquinone is halogenated at the 2 position in organic solvents or hydrochloric acid, in the 3 position in oleum or chlorosulfonic acid [173], and in the 5,8 positions in boric acid – oleum [174].

1-Alkylamino-5-hydroxyanthraquinones are halogenated preferentially in the 8 position in oleum [175] and only in the 4 position in hydrochloric acid [176].

A uniform monohalogenation product is not obtained from α-diaminodihydroxyanthraquinone. Choice of reaction conditions makes it possible to influence the isomer ratio (halogen next to amino or next to hydroxy groups).

1,5-Dihydroxy-4,8-dinitroanthraquinone is halogenated cleanly in the 2,6 positions in aqueous alkali [177]. In boric–sulfuric acid and in the presence of a 1,3-alkanediol, one of the nitro groups is replaced by a halogen [178].

Nucleus H → NO_2 . The rules for the course of the nitration of hydroxyanthraquinones are similar to those for the halogenation. Quinizarin in sulfuric acid or organic solvents is nitrated in the 2 position, whereas in boric acid–oleum one gets only nitration in the 5 position. A different behavior is shown by the boric or arsonic acid esters of 1,2-dihydroxyanthraquinone (alizarine). Here nitration in sulfuric acid yields the 3- and 4-nitro derivatives. 1,8-Dihydroxyanthraquinone in sulfuric acid is dinitrated up to 80 % in the 4 and 5 positions, whereas the isomeric 1,5-dihydroxy compound affords only unsatisfactory yields of 1,5-dihydroxy-4,8-dinitroanthraquinone.

The α-nitration is more successful with dimethoxyanthraquinones and yet more successful with diphenoxyanthraquinones. In the last case the benzene rings are also nitrated in their 2 and 4 positions, which then facilitates ether hydrolysis in alkaline medium:

Halogen → SO_3H. The remaining chlorine atom in 1,4-diamino-3-chloro-2-phenoxyanthraquinone (obtained from 1,4-diamino-2,3-dichloroanthraquinone by phenolate melt) is replaced readily in alkali sulfite to yield the sulfonic acid.

Halogen → NHR. Halohydroxyanthraquinones can be converted into the corresponding aminohydroxyanthraquinones by the methods cited under aminoanthraquinones (see page 8).

NO_2 → NHR (R = H, alkyl, aryl). The reduction of hydroxynitroanthraquinones is possible using the usual methods. A special industrial process is a reduction with elemental sulfur in oleum.

The nitro group of 1-hydroxy-4-nitroanthraquinone is replaced easily by amino residues. In α-dihydroxydinitroanthraquinones, a stepwise substitution presents no special difficulties. In 1,8-dihydroxy-4,5-dinitroanthraquinone, the reaction with aromatic amines in the presence of boric acid takes a different course. The product is 5,8-diarylamino-1-hydroxy-4-nitroanthraquinone [179].

A special reaction constitutes the conversion of α-nitroanthraquinones into the corresponding 1-amino-4-hydroxyanthraquinones mediated by the action of sulfur or other reducing agents, e.g., $FeSO_4$, in oleum or sulfuric acid monohydrate, if necessary with addition of boric acid. This reaction is accompanied by a number of side reactions. Satisfactory yields and purity levels are achieved only in exceptional cases [180], [181]; see also [13, pp. 199 – 203].

2.6.2. Individual Hydroxyanthraquinones

1,2-Dihydroxyanthraquinone [*8005-35-4*], alizarine, (**32**), M_r 240.2, *mp* 289 – 290 °C, is prepared from anthraquinone by alkali melt [182] or from anthraquinone-2-sulfonic acid with 50 % aqueous sodium hydroxide and sodium nitrate at 190 – 200 °C [3, p. 39], [5, p. 44].

32

33

1,4-Dihydroxyanthraquinone [*81-64-1*], quinizarin, (**33**), M_r 240.2, *mp* 198 °C, is prepared from phthalic anhydride and *p*-chlorophenol by heating in oleum in the presence of boric acid [1], [12]. Improved methods are cited in [183], [184].

1,5-Dihydroxyanthraquinone [*117-12-4*], anthrarufin, (**34**), M_r 240.2, *mp* 280 °C, is prepared from 1,5-anthraquinonedisulfonic acid by replacing the SO_3H groups [3, p. 16], [12] and from 1,5-dinitroanthraquinone by directly replacing the nitro groups, e.g., in sulfolane with calcium oxide [185] or, more effectively, via 1,5-dimethoxyanthraquinone and subsequent hydrolysis of the ether linkage [186].

34

1,8-Dihydroxyanthraquinone [*117-10-2*], chrysazin, (**35**), M_r 240.2, *mp* 193 °C, is prepared by replacing SO_3H [5, p. 46], by directly replacing nitro groups in sulfolane in the presence of calcium oxide [185], or, better, via 1,8-dimethoxyanthraquinone and subsequent hydrolysis of the ether [186].

35

36

1,2,4-Trihydroxyanthraquinone [*81-54-9*], purpurin, (**36**), M_r 256.2, *mp* 257 – 259 °C, is prepared from alizarine [5, p. 57], [187] or from quinizarin by oxidation [188].

1,4,5-Trihydroxyanthraquinone [*2961-04-8*], M_r 256.2, *mp* 270 – 271 °C, is prepared from 1,8-dihydroxyanthraquinone with 80 % oleum and boric acid [189].

1,4,5,8-Tetrahydroxyanthraquinone [*81-60-7*], M_r 272.2, *mp* above 300 °C, is prepared from 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulfonic acid by treatment with a mixture of sodium dithionite–sodium hydroxide in aqueous medium [12].

1,5-Dimethoxyanthraquinone [*6448-90-4*], (**37**), M_r 268.3, *mp* 236 °C, is prepared from anthraquinone-1,5-disulfonic acid with methanolic alkali-metal hydroxide [190] or from 1,5-dinitroanthraquinone with methanolic alkali-metal hydroxide in the presence of amidosulfonic acid [191] or by passing air through the reaction mixture [192], [193].

37

38

1,5-Diphenoxyanthraquinone [*82-21-3*], (**38**), M_r 392.4, *mp* 215 °C, is prepared from 1,5-dichloroanthraquinone and sodium phenolate without solvent [4, p. 8] or with an inert solvent [194] or from 1,5-dinitroanthraquinone by reaction with alkali phenolate in phenol [195] or an inert solvent [196], [197].

1,8-Dimethoxyanthraquinone [*6407-55-2*], M_r 268.3, *mp* 212 °C, is prepared from anthraquinone-1,8-disulfonic acid with methanolic alkali-metal hydroxide [190], from 1,8-dinitroanthraquinone with methanolic alkali-metal hydroxide in the presence of amidosulfonic acid [191], by passing air through the reaction mixture [192], [193].

1,8-Diphenoxyanthraquinone [*82-17-7*], M_r 392, *mp* 189 – 190 °C, is prepared from 1,8-dichloroanthraquinone [198] or 1,8-dinitroanthraquinone [195], [197] by reaction with alkali phenolate.

5,8-Dichloro-1,4-dihydroxyanthraquinone [*2832-30-6*], (**39**), M_r 309.1, *mp* 266 °C, is prepared from 3,6-dichlorophthalic anhydride by synthesis of the nucleus [199] or from quinizarin by chlorination [174].

39

2-Bromo-1,4-dihydroxyanthraquinone [*81-52-7*], (**40**), M_r 319.1, sublimation at 300 °C, is prepared from quinizarin by bromination in nitrobenzene [3, p. 66].

40

41

1-Hydroxy-4-nitroanthraquinone [*81-65-2*], (**41**), M_r 269.2, *mp* 268 °C, is prepared from 1-hydroxyanthraquinone in sulfuric acid monohydrate with nitric–sulfuric acid [200].

1,4-Dihydroxy-5-nitroanthraquinone [*27573-16-6*] M_r 285.2, *mp* 244 – 245 °C, is prepared from 1-hydroxy-10-chloroanthraquinone-(4,9) [201].

1,5-Dihydroxy-4,8-dinitroanthraquinone [*128-91-6*], M_r 330.2, is prepared from 1,5-diphenoxyanthraquinone by nitration followed by alkaline hydrolysis [4, p. 8].

1,8-Dihydroxy-4,5-dinitroanthraquinone [*81-55-0*], M_r 330.2, is prepared from 1,8-diphenoxyanthraquinone by nitration followed by alkaline hydrolysis or, alternatively, by nitration of 1,8-dihydroxyanthraquinone in oleum in the presence of boric acid and isolation after the sulfuric acid concentration has been adjusted to 80 – 100 % [202] or, using the same procedure,

from 1,8-dimethoxyanthraquinone followed by ether cleavage.

1-Amino-4-hydroxyanthraquinone [*116-85-8*], (**42**), M_r 239.2, *mp* 208 °C, is prepared from 1-amino-4-hydroxyanthraquinone-3-sulfonic acid by splitting off the SO_3H group [203], from 1-benzoylamino-4-chloroanthraquinone by treatment with boric–sulfuric acid, or from 1-nitroanthraquinone by reduction with $FeCl_2$ in sulfuric acid and rearrangement of the hydroxylamine stage [180], from 1,4-diaminoanthraquinone with MnO_2 in sulfuric acid [204], or from 1-hydroxyanthraquinone by nitration followed by reduction with Na_2S [5, p. 200].

42

3-Amino-1,2-dihydroxyanthraquinone [*3963-78-8*], M_r 255.2, *mp* above 300 °C, is prepared from the 3-nitro compound by reduction with Na_2S [3, p. 3].

4-Amino-1,3-dihydroxyanthraquinone [*81-51-6*], M_r 255.2, is prepared from 1,2,4-trihydroxyanthraquinone (purpurin) and NH_3 [13, p. 163].

5-Amino-1,4-dihydroxyanthraquinone [*23215-11-4*], M_r 255.2, is prepared from the 5-nitro compound by reduction with SO_2 [205].

3-Amino-2-hydroxyanthraquinone [*117-77-1*], (**43**), M_r 239.2, is prepared from 5-benzoylbenzoxazolone-2′-carboxylic acid [2, p. 14].

43

4,8-Diamino-1,5-dihydroxyanthraquinone [*145-49-3*], M_r 270.2, is prepared from 1,5-dihydroxy-4,8-dinitroanthraquinone by reduction with sodium sulfide; from 1,5-diphenoxyanthraquinone by nitration, cleavage, and reduction [4, p. 8]; a process improvement is described in [206]; or from 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulfonic acid by desulfonation [207].

4,5-Diamino-1,8-dihydroxyanthraquinone [*128-94-9*], M_r 270.2, is prepared from 1,8-dihydroxy-4,5-dinitroanthraquinone by reduction [208] or by cleavage of the sulfonic acid groups from the corresponding 2,7-disulfonic acid [207].

1-Hydroxy-5-isopropylaminoanthraquinone [*33902-49-7*], (**44**), M_r 281.3, is prepared from 1-isopropylaminoanthraquinone-5-sulfonic acid by replacement of SO_3H [175], [176].

44 **45**

1-Hydroxy-4-(*p*-methylphenylamino)anthraquinone [*81-48-1*], (**45**), M_r 329.4, is prepared from the leuco form of quinizarin and *p*-toluidine [209], [3, p. 48] or from 4-halo-1-hydroxyanthraquinone and *p*-toluidine.

1-Hydroxy-5,8-bis-(*p*-methylphenylamino)anthraquinone [*4392-68-1*], M_r 434.5, is prepared from 1,4,5-trihydroxyanthraquinone and *p*-toluidine [3, p. 33] by replacing hydroxyl or from 5,8-dichloro-1-hydroxyanthraquinone [210] by chlorine replacement.

1,4-Dihydroxy-5,8-bis(phenylamino)anthraquinone, (**46**), M_r 422.4, is prepared from 5,8-dichloro-1,4-dihydroxyanthraquinone and aniline [211] or from leuco-tetrahydroxyanthraquinone and aniline in water [212] or in pure aniline [213] with the addition of boric acid.

46 **47**

1-Methoxy-4-(*p*-methylphenylamino)anthraquinone, (**47**), M_r 343.4, is prepared by methylation of 1-hydroxy-4-(*p*-methylphenylamino)anthraquinone.

1,5-Dibenzoylamino-4-hydroxyanthraquinone [*6370-96-3*], M_r 462.4, is prepared by oxidation of 1,5-dibenzoylaminoanthraquinone with MnO_2 [214].

8-Benzoylamino-1,5-dihydroxy-4-(*p*-methoxybenzoylamino)anthraquinone, (**48**), M_r 508.4, is prepared by mixed acylation of 4,8-diamino-1,5-dihydroxyanthraquinone with *p*-methoxybenzoyl chloride and benzoyl chloride [4, p. 8].

48

49

1-Amino-4-hydroxy-2-hydroxyethoxyanthraquinone [*17869-07-7*], (**49**), M_r 299.3, is prepared from 1-amino-4-hydroxy-2-phenoxyanthraquinone by replacement of the phenoxy group [215], from the 2-chloro compound by replacement of chlorine [216], or from the 1,4-dihydroxy derivative with ammonia [217].

1,4-Diamino-2,3-diphenoxyanthraquinone [*6408-72-6*], (**50**), M_r 422.4, is prepared from the 2,3-dichloro compound and phenol by chlorine replacement [3, p. 49].

50

1-Amino-4-hydroxy-2-phenoxyanthraquinone [*17418-58-5*], (**51**), M_r 331.3, is prepared from 1-amino-2-chloro- (or -2-bromo-) 4-hydroxyanthraquinone and phenolate. This process was improved [218].

51

52

4,8-Diamino-1,5-dihydroxy-3-(*p*-methoxyphenyl)anthraquinone, (**52**), (for the elucidation of the structure see [169]), M_r 377.3, is prepared from 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulfonic acid by addition of anisole [219] and subsequent SO_3H removal [170] or from 4,8-diamino-1,5-dihydroxyanthraquinone via the iminoquinone and reaction with anisole [220].

4,8-Diamino-1,5-dihydroxy-2-(*p*-methoxyphenyl)anthraquinone [*4702-64-1*], (for the elucidation of the structure see [169]), M_r 377.3, is prepared from 1,5-dihydroxy-4,8-dinitroanthraquinone and anisole in boric–sulfuric acid followed by reduction [171].

1-Amino-5,8-dichloro-4-hydroxyanthraquinone [*2832-17-9*], (**53**), M_r 308.1, is prepared from 1-amino-4-hydroxyanthraquinone by chlorination in oleum–boric acid [180] or from 1-amino-4,5,8-trichloroanthraquinone with boric–sulfuric acid [221].

53

54

1-Amino-3-bromo-4-hydroxyanthraquinone, (**54**), M_r 318.1, is prepared from 1-amino-4-hydroxyanthraquinone and bromine in chlorosulfonic acid [173].

1-Amino-2-bromo-4-hydroxyanthraquinone [*116-82-5*], M_r 318.1, is prepared from 1-amino-2,4-dibromoanthraquinone with boric–sulfuric acid [3, p. 5] or in a one-pot process from 1-aminoanthraquinone (bromination – hydrolysis) [222–224].

8-Bromo-1-hydroxy-5-isopropylamino-anthraquinone, (**55**), M_r 360.2, is prepared by bromination [175].

55

56

1,8-Dihydroxy-5-nitro-4-phenylamino-anthraquinone, (**56**), M_r 376.3, is prepared from 1,8-dihydroxy-4,5-dinitroanthraquinone and aniline [225].

1,2-Dihydroxyanthraquinone-3-sulfonic acid [*83-61-4*], (**57**), M_r 320.3, is prepared from 1,2-dihydroxyanthraquinone with fuming sulfuric acid [226].

57

1,4-Dihydroxyanthraquinone-2-sulfonic acid [*145-48-2*], M_r 320.3, is prepared from 1,4-dihydroxyanthraquinone with sodium hydrogen sulfite and oxidizing agents [3, p. 65] or by sulfonation in oleum [227].

1,5-Dihydroxyanthraquinone-2,6-disulfonic acid [*6492-85-9*], M_r 400.3, is prepared from 1,5-dihydroxyanthraquinone with oleum–Na_2SO_4 [228].

1,8-Dihydroxyanthraquinone-2,7-disulfonic acid, M_r 400.3, is prepared by heating 1,8-dihydroxyanthraquinone in oleum [229].

1,5-Dihydroxy-4,8-dinitroanthraquinone-2,6-disulfonic acid [*6449-09-8*], (**58**), M_r 490.3, is prepared from 1,5-dihydroxyanthraquinone-2,6-disulfonic acid by nitration in sulfuric acid [228].

58

59

1,8-Dihydroxy-4,5-dinitroanthraquinone-2,7-disulfonic acid [*128-90-5*], (**59**), M_r 490.3, is prepared from 1,8-dihydroxyanthraquinone-2,7-disulfonic acid by nitration [229].

4,8-Diamino-1,5-dihydroxyanthraquinone-2-sulfonic acid [*5138-23-8*], (**60**), M_r 350.3, is prepared by removal of one SO_3H group from the 2,6-disulfonic acid [207], [230].

60

61

4,8-Diamino-1,5-dihydroxyanthraquinone-2,6-disulfonic acid [*128-86-9*], (**61**), M_r 430.3, (the sodium salt is the dye Acilan Sapphirol B), is prepared from 1,5-dihydroxyanthraquinone by sulfonation, nitration, and reduction [1, p. 607].

4,5-Diamino-1,8-dihydroxyanthraquinone- 2,7-disulfonic acid, M_r 430.3, is prepared from 1,8-dihydroxyanthraquinone by sulfonation, nitration, and reduction [229].

2.7. Mercaptoanthraquinones

Mercaptoanthraquinones are of little commercial importance. However, they appear as unisolated intermediates. They are obtained by replacement of halogen [231] or sulfonic acid groups with alkali sulfides, by addition of alkali sulfides to 1-aminoanthraquinones [232], or by cleavage of thiocyanatoanthraquinones [233].

More important are the anthraquinone thioethers, which are obtained by usual methods as replacement of halogen, nitro, or sulfonic acid groups; by modification of mercaptoanthraquinones; or by addition reactions to hydroxy- and aminoanthraquinones or to quinoneimine derivatives [234]. 1-Hydroxy-4-nitroanthraquinones react especially well under simultaneous reduction of the nitro group [235].

2.7.1. General Aspects

$SO_3H \rightarrow SR$ (R = alkyl, aryl). The exchange of sulfonic acid groups against mercapto groups is especially suitable for the preparation of alkylmercaptoanthraquinones. The preparative reactions are carried out in aqueous alkaline medium at temperatures up to 100 °C.

Halogen → SR (R = H, alkyl, aryl). Halogen displacement is used to prepare mercapto-, alkylmercapto-, and arylmercaptoanthraquinones. Suitable reaction media are organic solvents: halogenated aromatic hydrocarbons and especially amides in the presence of acid binding agents, such as alkali – metal carbonates and tertiary amines.

$NO_2 \rightarrow SR$. Displacement of nitro groups occurs under conditions similar to those for the replacement of halogens, insofar as addition reactions do not predominate [236].

H → SR. The addition of mercaptans to amino- or hydroxyanthraquinones or to 1-hydroxy-4-nitroanthraquinones [235] that occurs via reductive steps has no industrial importance.

SH → SR. Mercaptoanthraquinones may be converted to alkylmercaptoanthraquinones with the usual alkylating agents under alkaline conditions [237].

2.7.2. Individual Mercapto Compounds and Thioethers

1,4-Diamino-2-mercaptoanthraquinone, (**62**), M_r 270.3, is prepared from 1,4-diamino-2-bromoanthraquinone and sodium disulfide followed by reduction [238].

62

63

1-Amino-2-(2-hydroxyethylmercapto)-4-phenylaminoanthraquinone, (**63**), M_r 390.4, is prepared by displacement of SO_3H from the corresponding anthraquinone-2-sulfonic acid [239].

1,4-Dihydroxy-2-phenylmercaptoanthraquinone, (**64**), M_r 348.4, is prepared from 1,4-dihydroxyanthraquinone and thiophenol [240].

64

65

1,8-Dihydroxy-4-nitro-5-phenylmercaptoanthraquinone, (**65**), M_r 393.4, is prepared from 1,8-dihydroxy-4,5-dinitroanthraquinone and thiophenol [236].

66

1-Amino-4-hydroxy-2-phenylmercaptoanthraquinone, (**66**), M_r 347.4, is prepared by displacement of bromine from 1-amino-2-bromo-4-hydroxyanthraquinone and thiophenol [241].

1-Amino-2-mercaptoanthraquinone-6-sulfonic acid, (**67**), M_r 335.4, is prepared from 1-nitroanthraquinone-6-sulfonic acid with aqueous sodium sulfide [242].

67

68

1,4-Dihydroxy-2-(2-hydroxyethylmercapto)anthraquinone [*3319-54-8*], (**68**), M_r 316.3, is prepared from 2-nitro-, 2-halo-, or 2-sulfo-1,4-dihydroxyanthraquinone with 2-mercaptoethanol [243].

2.8. Anthraquinonesulfones

Alkyl and aryl sulfone derivatives of anthraquinone have reached a certain amount of importance only as polyester dyes resistant to sublimation and as dyes for mixed polyester – cotton

fabrics. They are obtained by displacement of the halo [244] or nitro group with sulfinates, by sulfinic acid addition to quinoneimines [245], or by oxidation of the corresponding thioethers with chromium(VI) oxide or hydrogen peroxide in such solvents as glacial acetic acid or sulfuric acid [246].

1-Amino-2-phenylsulfonyl-4-*p*-tosylaminoanthraquinone (**69** with $R^1 = -SO_2C_6H_4CH_3$, $R^2 = -C_6H_5$), M_r 456.6, is prepared from the 2-bromo compound by halogen displacement with benzene sulfinate [244].

1-Amino-2-ethylsulfonyl-4-(*p*-isopropylphenylamino)anthraquinone [*4839-56-9*], (**69** with $R^1 = -C_6H_4CH(CH_3)_2$, $R^2 = -C_2H_5$), M_r 448.5, is prepared from the 2-bromo compound by halogen displacement with ethyl sulfinate [237].

4,8-Diamino-1,5-dihydroxy-2- (and -3-) phenylsulfonylanthraquinone (**70** with $R = C_6H_5$), M_r 410.4, is prepared from 4,8-diamino-1,5-dihydroxyanthraquinone via the quinoneimine [245].

2.9. Anthraquinone Aldehydes and Their Derivatives

Only anthraquinone-2-aldehydes and their derivatives have industrial importance. Starting materials are mainly methylanthraquinones, which are converted by direct oxidation with manganese dioxide or chromic acid [248] or via the dihalomethyl compounds [249] into the aldehydes. In industrial processes, 1-amino-2-methylanthraquinone is oxidized with nitrobenzene in the presence of aniline. The azomethine formed in this step can be hydrolyzed easily to the aldehyde but usually is used directly in further reactions.

1-Aminoanthraquinone-2-aldehyde also may be prepared from 2-methyl-1-nitroanthraquinone by reaction with 65 % oleum followed by reduction of the resulting isoxazole [250].

1-Aminoanthraquinone-2-aldehyde, M_r 251.2, is prepared by oxidation of 1-amino-2-methylanthraquinone with nitrobenzene in the presence of aniline and potassium carbonate, followed by hydrolysis of the 1-aminoanthraquinone-2-aldehyde anil in sulfuric acid [251], or by action of 65 % oleum on 2-methyl-1-nitroanthraquinone followed by reduction [250].

1-Amino-4-benzoylaminoanthraquinone-2-aldehyde anil, (**71**), M_r 445.5, is prepared from 1-amino-4-benzoylamino-2-methylanthraquinone by oxidation in nitrobenzene in the presence of aniline and potassium carbonate [252].

The azine of 1-amino-4-benzoylaminoanthraquinone-2-aldehyde, (**72**), M_r 736.6, is prepared from the aldehyde anil in glacial acetic acid with hydrazine hydrate [252].

72

2.10. Anthraquinonecarboxylic Acids and Carboxylic Acid Derivatives

Whereas carboxylic acid and carbonyl chloride groups linked directly to the anthraquinone nucleus rarely appear outside the realm of dyestuff intermediates, the carboxylic esters, amides, imides, azoles, and nitriles exist in dyestuffs.

Anthraquinonecarboxylic acids may be obtained by ring closure of the corresponding *o*-benzoylbenzoic acids, by oxidation of methylanthraquinones, or by hydrolysis of nitriles. The derivatives are prepared from the carboxylic acids or nitriles by the usual methods. The nitrile group may be introduced by displacing the halogen or sulfonic acid group, or by addition.

2.10.1. General Aspects

Synthesis of Nucleus. Benzophenone dicarboxylic acids may be cyclized in weak oleum at 110–120 °C. This is the method used to prepare anthraquinone-2-carboxylic acid and 3-chloroanthraquinone-2-carboxylic acid.

$CH_3 \rightarrow COOH$. 2-Methylanthraquinone can be converted into anthraquinone-2-carboxylic acid by an oxidizing agent, such as chromic acid, in dilute sulfuric acid. Oxidation of the isoxazole obtained from 2-methyl-1-nitroanthraquinone yields the 1-nitroanthraquinone-2-carboxylic acid.

$SO_3H \rightarrow CN$. 1,4-Diaminoanthraquinone-2-sulfonic acid is converted to 1,4-diamino-2,3-dicyanoanthraquinone by reaction with alkali cyanides in aqueous alkaline medium and in the presence of an oxidant, such as manganese dioxide. From 1,4-diaminoanthraquinone-2,3-disulfonic acids are also formed the corresponding 2,3-dicyano compounds.

A related reaction is the formation of 1,4-diaminoanthraquinone-2,3-*N*-alkyliminodicarboxylic imides (**73**) from 1-amino-4-nitroanthraquinone-2-carboxylic amides on reaction with cyanides followed by reduction [253].

73

Halogen $\rightarrow$ CN. A general method for preparing cyanoanthraquinones is the displacement of halogen with CuCN in an organic solvent, such as benzyl cyanide, dimethylformamide, or quinoline.

$CN \rightarrow CONH_2 \rightarrow COOH$. Cyanoanthraquinones are hydrolyzed by the action of mineral acids or alkalies to yield the corresponding carboxamides or the free carboxylic acids, depending on the conditions.

Iminoimides (**74**), imides (**75**) [254], anhydrides, or free dicarboxylic acids are formed from 2,3-dicyanoanthraquinones. Reaction with alcoholic alkali forms the corresponding methoxyimino imides (**74,** R=CH_3) [255].

74

75

These hydrolysis products may be reacted further with amines.

$COOH \rightarrow COCl \rightarrow COOR$ or $CONR_2$. Anthraquinonecarboxylic acids may be converted by the usual methods (reaction with thionyl chloride or phosphorus halides) to their

acid chlorides and further to carboxylic esters and amides. Depending on their substituents, the carboxylic arylamides and hydrazides may be converted to azoles. For example, anthraquinonedicarboxylic acid dihydrazides are converted into the corresponding oxazoles.

$H \rightarrow NO_2$ or Halogen. 1-Aminoanthraquinone-2-carboxylic acid may be nitrated or halogenated in the 4 position in sulfuric acid [256]. However, under these conditions, anthraquinone-2-carboxylic acid is nitrated or dichlorinated in the 5,8 positions.

$Cl \rightarrow NHR$, $NO_2 \rightarrow SO_3H$, NHR. Carboxyl groups and their derivatives facilitate the replacement of nitro groups or halogen atoms by a variety of substituents.

$SO_3H \rightarrow Cl$. The sulfonic acid group of 2-carboxyanthraquinone-1-sulfonic acid, which is obtained from 1-nitroanthraquinone-2-carboxylic acid, is replaced easily by halogen.

2.10.2. Individual Anthraquinonecarboxylic Acids

Anthraquinone-2-carboxylic acid [*117-78-2*], M_r 252.5, is prepared from 4′-methylbenzophenone-2-carboxylic acid by oxidation with potassium permanganate and ring closure with 5 % oleum [3, pp. 8, 12].

1-Chloroanthraquinone-2-carboxylic acid [*82-23-5*], M_r 286.7, is prepared by Fischer reaction from 2-carboxyanthraquinone-1-sulfonic acid [257].

3-Chloroanthraquinone-2-carboxylic acid [*84-32-2*], M_r 286.7, is prepared from 3′-chloro-4′-methylbenzophenone-2-carboxylic acid by oxidation with potassium permanganate in alkaline solution, followed by ring closure in oleum [4, p. 19].

1-Nitroanthraquinone-2-carboxylic acid [*128-67-6*], (**76**), M_r 297.2, is prepared from 2-methyl-1-nitroanthraquinone by oxidation in sulfuric acid with sodium dichromate [2, p. 13], [5, p. 69] or in nitric acid with chromic acid [258].

76

77

1,4-Diamino-2,3-dicyanoanthraquinone [*81-41-4*], (**77**), M_r 288.2, is prepared from 1,4-diaminoanthraquinone-2-sulfonic acid [259], [260] or from 1,4-diaminoanthraquinone-2,3-disulfonic acid in aqueous alkaline solution [261] or in amides [262] by reaction with sodium cyanide.

1-Amino-2-cyano-4-cyclohexylamino-anthraquinone, (**78**), M_r 345.4, is prepared by displacement of SO_3H with potassium cyanide in aqueous solution [3, p. 56].

78

79

1-Aminoanthraquinone-2-carboxylic acid [*82-24-6*], (**79**), M_r 267.2, is prepared from 1-nitroanthraquinone-2-carboxylic acid with ammonia [2, p. 17] or from 2-methyl-1-nitroanthraquinone [263].

3-Aminoanthraquinone-2-carboxylic acid [*4831-47-4*], M_r 267.2, is prepared from 3-chloroanthraquinone-2-carboxylic acid with ammonia [4, p. 19].

1-Amino-4-cyclohexylaminoanthraquinone-2carboxamide [*3443-93-4*], (**80**), M_r 363.4, is prepared by partial hydrolysis of the nitrile [3, p. 57].

80

81

Ethyl-1,4-diaminoanthraquinone-2-carboxylate, (**81**), M_r 310.3, is prepared from 1-

amino-4-nitroanthraquinone-2-carbonyl chloride and ethanol followed by reduction [264].

1-Amino-4-nitroanthraquinone-2-carboxylic acid [*2058-02-8*], (**82**), M_r 312.2, is prepared by nitration of 1-aminoanthraquinone-2-carboxylic acid in sulfuric acid–formaldehyde [2, p. 17].

82

83

1,4-Diaminoanthraquinone-2,3-dicarbonyl imide [*128-81-4*], (**83**), M_r 307.3, is prepared from the corresponding dinitrile [254] or from 1,4-diaminoanthraquinone-2-carboxamide and NaCN in dimethylformamide with aeration [265].

84

2-Carboxyanthraquinone-1-sulfonic acid, (**84**), M_r 332.3, is prepared from 1-nitroanthraquinone-2-carboxylic acid with Na_2SO_3 in aqueous solution [257].

2.11. Anthraquinone Derivatives with Condensed Rings

Anthraquinone derivatives with carbocyclic condensed rings, e.g., (**85**), have not yet become important as dye building blocks; however, anthraquinone structures with heterocyclic condensed rings are important components of many vat dyes and also of disperse dyes and pigments. Phthaloyl carbazoles, especially the anthrimide carbazoles, such as **86**, represent by far the most important class of compounds. Other heterocyclic systems used industrially include imidazole, oxazole, and thiazole derivatives (**87**); the phthaloyl acridones (anthraquinone acridone, **88**); and the azine derivatives of anthraquinone (indanthrone, **89**).

85

86

X = NH, O, S **87**

88

89

2.11.1. Anthraquinone Derivatives Containing Imidazole, Oxazole, and Thiazole Rings

Anthraquinone dyes with condensed imidazole, oxazole, or thiazole rings are prepared by dehydrating ring closure from 2-aroylaminoanthraquinones that carry an amino, hydroxy, or mercapto group in positions 1 or 3.

X = NH, O, S

Anthraquinone derivatives with condensed imidazole rings are the least important. The bisimidazole **90** prepared from 1,2-diaminoanthraquinone and terephthalyl chloride [266], [267] is a yellow vat dye.

90

More important are the oxazole and thiazole derivatives. These are prepared from 2-hydroxy- (or 2-halo-) 3-aminoanthraquinones and 1-nitro- (or 1-amino-) anthraquinone-2-carboxylic acid [268] or 1-amino-4-nitroanthraquinone-2-carboxylic acid.

Whereas the oxazole derivatives are obtained directly from the 3-amino-2-hydroxyanthraquinone by acylation followed by ring closure with sulfuric acid [269], the preparation of the thiazoles requires acylation of 3-chloro-2-aminoanthraquinone followed by displacement of chlorine by a mercapto group using sodium sulfide, with simultaneous reduction of the 1-nitro group. Concentrated sulfuric acid is used for the ring closure in the same manner as for the oxazoles.

2-(1-Amino-2-anthraquinonyl)anthra [2,3-*d*-] oxazole-5,10-quinone [*2379-79-5*], Indanthren Red FBB, (**91**), M_r 470.4, is prepared by reacting 1-nitroanthraquinone-2-carbonyl chloride and 2-amino-3-hydroxyanthraquinone, followed by displacement of the nitro group with ammonia and ring closure [2, p. 15], [269].

91

The following are the corresponding thiazole compounds: Indanthren Rubine B [*6371-49-9*], (**92**), [2, p. 15, 16], M_r 486.5; Indanthren Blue CLG [*6371-50-2*], (**93**), [2, p. 18], [270], M_r 605.6; and Indanthren Blue CLB [*6492-78-0*], (**94**), [2, p. 18], [271], M_r 673.6. Compound **94** is prepared from 1-amino-4-nitroanthraquinone-2-carbonyl chloride and 2-amino-3-chloroanthraquinone and Na_2S-sulfur.

92, R = H

93, R = -NH-CO-

94, R = -NH-CO-

2,2′-Bisanthra [2,1-*d*-] thiazole-6,11-quinonyl [*6451-12-3*], Algol Yellow 8 G, (**95**), M_r 528.6, is prepared from 2-amino-1-chloroanthraquinone by replacing the chlorine atom by a mercapto group, followed by reaction with glyoxal sulfate in concentrated sulfuric acid [272], [2, p. 19].

95

96

2,8-Diphenylthiazolo [5′,4′ : 7,8] anthra-[2,1-*d*-] thiazole-6,12-quinone [*129-09-9*], Algol Yellow GC, (**96**), M_r 474.6, is prepared from 2,6-diaminoanthraquinone and benzaldehyde [273] or benzotrichloride [2, p. 59] and sulfur in molten naphthalene.

2.11.2. Anthraquinonecarbazole Derivatives

The following description uses the designations common in industrial circles. The carbazole of 1,1′-dianthrimide is referred to as 1,1′-dianthrimide-2,2′-carbazole. Other terms for this carbazole would be: 1,2 : 7,8-diphthaloylcarbazole, 16*H*-dinaphtho [2,3-*a* : 2′,3′-*i*] carbazole-5,10,15,17-tetraone, and 16*H*-(bis{anthraceno-[1,2-*b* : 2′,1′-*d*] pyrrole}) 5,17 : 10,15-bisquinone.

1-Arylaminoanthraquinones may be condensed to coeramidonine derivatives, or they may be subjected to a dehydrogenating cyclization to give carbazole derivatives.

Coeramidonines are generally obtained on heating in aqueous sulfuric acid. When simple 1-arylaminoanthraquinones are treated with aluminum chloride, frequently both types of products are obtained [274]. Naphthylaminoanthraquinones and anthrimides tend to form carbazole derivatives. The reaction proceeds via dihydrocarbazoles, which are converted to the corresponding carbazoles by subsequent oxidation with air, sodium dichromate, manganese dioxide, sodium chlorate, sodium nitrite, or sodium hypochlorite. The dehydrogenating cyclization is generally termed *carbazolyation*.

86

Among the carbazole derivatives that are not derived from anthrimides, Alizarin Light Brown BL (**97**) is an example. It is prepared from 1-benzoylamino-2-methyl-4-β-naphthylaminoanthraquinone by ring closure in concentrated sulfuric acid with simultaneous sulfonation [275].

97

The vast majority of industrial carbazoles are derivatives of α,α'-anthrimides. They include some of the most important anthraquinone dyes with condensed heterocyclic rings. They are used mainly as vat dyes. They have good to excellent coloristic properties in this application and are used for yellow, orange, brown, olive, and gray colors. The particular shade depends on the number of linked anthraquinone moieties, on whether the linkage is linear or branched, and on the nature of the substituents. They are prepared industrially by carbazolyation of di-, tri-, tetra-, and pentanthrimides. Even if carbazolyation products of the higher anthrimides are generally cited as pure single compounds, carbazolyation reaction in many polyanthrimides by the usual methods must be considered incomplete.

In its broadest sense, the term anthrimide includes secondary amines, where anthraquinone has been replaced by anthraquinone derivatives such as benzanthrone, anthrapyrimidine, pyrazolanthrone, and phthaloylacridone.

Carbazolyation of anthrimide can be carried out with strong protic acids, metal halides, or alkali–metal hydroxides. The acid most commonly used is concentrated sulfuric acid, but chlorosulfonic acid or weak oleum are used also [276]. Anhydrous hydrogen fluoride in the presence of manganese dioxide also has been proposed [277]. Of the recommended metal halides ($AlCl_3$, $FeCl_3$ [278], $ZnCl_2$, $TiCl_4$, $SnCl_4$, etc.) the most frequently used is aluminum chloride. Carbazolyation in pure molten aluminum chloride has been used successfully but leads to rather contaminated products because of the temperatures required (200 – 280 °C) [279] and is not practical because of the difficulties in mixing the components intimately. The physical and chemical properties of the melts have been modified by a variety of additives. In the so-called acid melts, alkali–metal halides (NaCl, NaF, KCl), sulfur dioxide [281], sodium hydrogen sulfite,

organic solvents [282], nitrobenzene (danger of explosion!) [283], nitriles [285], or acid chlorides [286] have been proposed. The so-called alkaline aluminum chloride melts are obtained by addition of excess pyridine, picolines, quinolines, isoquinolines, or dimethylaniline [287]. Aluminum chloride–pyridine complexes in a molar ratio of $\geqq 1:1$ [288], possibly in the presence of organic solvents, and with aluminum chloride–ammonia complexes, are equivalent in their mode of action to the acid melts [289]. Carbazolyation with titanium tetrachloride in organic solvents, such as halobenzenes [290] or, sulfolane [291], have been described. Finally, alkaline carbazolyation in potassium hydroxide melts, possibly with addition of sodium hydroxide, has been reported also [292].

Each of the carbazolyation agents possesses specific properties and modes of action. The choice of an optimal carbazolyation process depends largely on the structure of the anthrimide and the nature of the substituents.

The following carbazolyation agents are used commercially:

1) *Sulfuric acid:* benzoylamino groups in the α-position and an acridone substructure facilitate carbazolyation in concentrated sulfuric acid. For example, the 4,4′-, 4,5′-, and 5,5′-dibenzoylamino-1,1′-dianthrimides; 4,5-dibenzoylamino-8-methoxy-1,1′-dianthrimide; and the anthrimide prepared from 1-amino-5-benzoylaminoanthraquinone and the 2,5,7-trichloro-3,4-phthaloylacridone are carbazolated in this way. The reactions are carried out by adding the anthrimide to sulfuric acid and stirring at 20–40 °C until reaction is complete, which is generally indicated by a change in the color of the solution. The melt is then poured into water, and the dihydrocarbazole oxidized. Posttreatment with sodium dichromate, sodium nitrite, sodium persulfate, sodium chlorate, or sodium hypochlorite facilitates a certain degree of purification by oxidizing impurities.
2) *Aluminum chloride–alkali metal halide:* mixtures of aluminum chloride and dry sodium chloride (weight ratio $\approx 4:1$) form relatively low melting eutectics. Such melts are used mainly for the carbazolyation of 1,1′-dianthrimide, 1,1′ : 5,1″-trianthrimide, and 1,1′ : 4,1″ : 5,1‴ : 8,1⁗-pentanthrimide at 140–220 °C. Stirring the melt into a solution of sodium hydroxide or hydrochloric acid, followed by oxidation with sodium dichromate, for example, yields the dyes.
3) *Aluminum chloride–sulfur dioxide:* melts of aluminum chloride and sulfur dioxide, to which sodium chloride can be added if necessary, have low viscosity and permit carbazolyation under mild conditions (20–100 °C). This method is superior to other carbazolyation processes in some cases, for instance, in treating 4′,4″-dibenzoylamino-1,1′ : 5,1″-trianthrimide. The reagent is prepared by passing sulfur dioxide into a melt of aluminum chloride and sodium chloride (weight ratio $\approx 4:1$) until the melt has low viscosity. After the anthrimide is added, the mixture is heated to the temperature required for carbazolyation. Workup involves stirring into sodium hydroxide solution.
4) *Aluminum chloride–pyridine (or methylpyridines):* carbazolyation in aluminum chloride–pyridine melts (excess pyridine) is applicable to many substituted and unsubstituted anthrimides. Industrially, this method is applied mainly to 1,1′ : 4,1″-trianthrimide, 5-benzoylamino-1,1′ : 4,1″-trianthrimide, 5-(benzanthron-3-ylamino)–1,1′-dianthrimide, and 1-benzoylamino-4,1′ : 5,1″ : 8,1‴-tetraanthrimide. In this process, aluminum chloride is added to pyridine (weight ratio $\approx 1:5$) first, and then the anthrimide is added. After heating to the temperature required for the carbazolyation, 100–170 °C, and stirring until reaction is completed, workup is carried out by adding to sodium hydroxide solution, and, if necessary, oxidative cleanup. The type of organic base (pyridine, methylpyridine, quinoline, etc.) selected and the reaction conditions exert a decisive influence on the quality of the dye.

Some important members of the anthraquinonecarbazole series are listed below.

1,1′-Dianthrimide-2,2′-carbazole [*4229-15-6*], Indanthren Yellow FFRK, M_r 427.4 (for formula see above), is prepared from

1,1′dianthrimide in $AlCl_3$-NaCl melts [4, p. 53] or in $AlCl_3$ – pyridine melts [287].

1,1′ : 5,1″-Trianthrimide-2,2′ : 6,2″-carbazole [*2172-33-0*], Indanthren Yellow 3 R, M_r 646.6, is prepared from 1,1′ : 5,1″-trianthrimide in $AlCl_3$-NaCl melts [2, p. 121].

1,1′ : 4,1″-Trianthrimide-2,2′ : 3,2″-carbazole [*2475-33-4*], (Indanthren Brown BR, *M* 646.6, is prepared from 1,1′ : 4,1″-trianthrimide in $AlCl_3$ – pyridine [5, p. 101].

1,1′ : 4,1″ : 5,1‴ : 8,1⁗-Pentanthrimide-2,2′ : 3,2′ : 6,2‴ : 7,2⁗-carbazole [*14999-97-4*], Indanthren Khaki GG, M_r 1085.0 (for formula see Section 3.1.3, **210**), is prepared from the corresponding pentanthrimide with aluminum chloride [278] or with aluminum chloride–sodium chloride [5, p. 133], [293].

5,5′-Bisbenzoylamino-1,1′-dianthrimide-2,2′carbazole [*128-70-1*], Indanthren Golden-Orange 3 G, M_r 665.6, is prepared from 5,5′-bisbenzoylamino-1,1′-dianthrimide by ring closure in concentrated sulfuric acid [4, p. 15].

4,5′-Bisbenzoylamino-1,1′-dianthrimide-2,2′carbazole [*131-92-0*], Indanthren Brown R, M_r 665.6, is prepared from 4,5′-bisbenzoylamino-1,1′-dianthrimide by ring closure in concentrated sulfuric acid [4, p. 10].

4,4′-Bisbenzoylamino-1,1′-dianthrimide-2,2′-carbazole [*2379-81-9*], Indanthren Olive R, M_r 665.6, is prepared from 4,4′-bisbenzoylamino-1,1′-dianthrimide by ring closure in concentrated sulfuric acid [4, p. 29].

4,4″-Bisbenzoylamino-1,1′ : 5,1 ″-trianthrimide-2,2′ : 6,2 ″-carbazole [*6487-07-6*], Indanthren Red Brown GR, (**98**), M_r 884.8, is prepared from the corresponding trianthrimide in aluminum chloride–sulfur dioxide [4, p. 42], [281].

98

2.11.3. Anthraquinone Derivatives with Acridone Substructure (Phthaloylacridones)

The red to blue anthraquinone dyes with acridone substructure are all derived from 3,4-phthaloylacridone (**99**). Their use has been mainly as vat dyes.

The basic structure provides red-violet dyes, but with rather weak tinctorial strength. The 3,4-phthaloylacridones are prepared from the 1-arylaminoanthraquinone-*o*-carboxylic acids **100** or **101** by acid-catalyzed ring closure using sulfuric acid, weak oleum, chloro- or fluorosulfonic acid, polyphosphoric acid, or $AlCl_3$ or to a lesser extent phosgene, acetyl chloride, or phosphoryl chloride.

Special methods for ring closure are the chlorination of 1-anilino-2-methylanthraquinone, which yields 1,2,5,6,7,8-hexachloro-3,4-phthaloylacridone [294], [295], and the acridone ring closure that occurs on vatting of 1-anilinoanthraquinone-2′-carboxylate esters [296].

The phthaloylacridones are chlorinated easily. Depending on the chlorination conditions, the unsubstituted 3,4-phthaloylacridone may be chlorinated in the 2,5,7 positions when Cl_2–nitrobenzene–I_2 is used or in the 5,7,8 positions when Cl_2–chlorosulfonic acid is used [297]. The chlorine in position 2 of 2,5,7-trichloro-3,4-phthaloylacridone is replaced easily by amines. Therefore, 2,5,7-trichloro-3,4-phthaloylacridone reacts with aminoanthraquinones to form anthrimides [298].

Bromamine acid and (substituted) anthranilic acid are used in the preparation of (substituted) 2-amino-3,4-phthaloylacridone (**102**). Ring closure in acid medium (oleum or chlorosulfonic acid) and cleavage of the sulfonic acid group yield 2-amino-3,4-phthaloylacridone.

3,4-Phthaloylacridone, (**103**), M_r 325.3, is prepared from 1-anilinoanthraquinone-2-carboxylic acid [299], [300] or from 1-(2′-carboxyphenylamino)anthraquinone [301].

2,5,7-Trichloro-3,4-phthaloylacridone [*6373–31–5*], Indanthren Red Violet RRK, (**104**), M_r 428.6, is prepared by chlorination of 3,4-phthaloylacridone in nitrobenzene with sulfuryl chloride [302].

5,7,8-Trichloro-3,4-phthaloylacridone, (**105**), M_r 428.6, is prepared by chlorination of 3,4-phthaloylacridone in chlorosulfonic acid in the presence of sulfur [297] or from the 5,7-dichloro compound [303].

1,2,5,6,7,8-Hexachloro-3,4-phthaloylacridone [*1328-35-4*], (**106**), Indanthren Pink B, M_r 532.0, is prepared by chlorination of 1-anilino-2-methylanthraquinone in trichlorobenzene followed by hydrolysis [294].

6-Chloro-2-amino-3,4-phthaloylacridone [*6219-98-3*], (**107**), Indanthren Turquoise Blue GK, M_r 374.8, is prepared from 1-amino-4(2′-carboxy-5′-chlorophenylamino)anthraquinone-2-sulfonic acid by ring closure in weak oleum and cleavage of the sulfonic acid group [4, p. 21].

2-Benzoylamino-6-trifluoromethyl-3,4-phthaloylacridone [*6219-97-2*], Indanthren Blue HCGK, (**108**), M_r 512.4, is prepared from bromamine acid (**12**) and 4-trifluoromethylanthranilic acid followed by ring closure and desulfonation in sulfuric acid monohydrate [4, p. 34], [5, p. 143].

1,2 : 5,6-Diphthaloylacridone [*10142-57-1*], Indanthren Orange F 3 R, (**109**), M_r 455.4, is prepared from 1-nitro- (or chloro-) anthraquinone-2-carboxylic acid and 2-aminoanthraquinone in dichlorobenzene followed by ring closure in sulfuric acid [304].

109

110

Indanthren Green 4 G [*6661-46-7*], (**110**), M_r 709.1, is prepared from 2-amino-7-chloro-3,4-phthaloylacridone and 2-phenyl-4-chloro-6,7-phthaloylquinazoline, which itself is derived from 3-aminoanthraquinone-2-carboxylic acid, benzoic acid, and ammonia [4, p. 19], [305].

2.11.4. Anthraquinone Derivatives with Phenazine Substructure

Among the anthraquinone derivatives with phenazine substructure, the *indanthrones* are an important class of vat dyes. The blue color of the unsubstituted unit may be shifted to green by appropriate substitutions. Several synthetic pathways are available:

1) Aminoanthraquinones are dimerized to indanthrones in alkali melts (above 200 °C) in the presence of such oxidizing agents as sodium nitrite or air. The oldest and most important method for preparing unsubstituted indanthrone is the potash fusion of 2-aminoanthraquinone. A related process is the oxidation of the leuco-sulfuric ester of 2-aminoanthrahydroquinones in sodium hydroxide with potassium permanganate [306]. However, this preparation method is useful only for the preparation of leuco-sulfuric esters of indanthrones.
   Better suited for the oxidative dimerization of 1-aminoanthraquinone to indanthrone is a melt of potassium phenolate at 200 – 210 °C in the presence of oxidizing agents [308] or passage of air in the presence of catalysts, such as MnO_2 or $FeCl_3$ [309]. Dimerization of 1- (or 2-) aminoanthraquinone to indanthrone can be achieved with good yields at 115 – 125 °C in mixtures of dimethyl sulfoxide [310] or tetramethylurea [311] and 50 % aqueous KOH.
2) 2-Amino-1-halo- (or 1-amino-2-halo-) anthraquinones condense to indanthrones when heated in high-boiling solvents, such as nitrobenzene or naphthalene, in the presence of copper or copper salts and acid-binding agents (Kugel's indanthrone synthesis) [312]. This method, however, is important only in the preparation of substituted indanthrones.

Indanthrone [*81-77-6*], Indanthren Blue RS and R, (**111**), M_r 442.4, is prepared from 2- (or 1-) aminoanthraquinone by potash fusion [1, p. 712], in potassium phenolate [307], [309], or in 50 % potassium hydroxide [211], [310].

111

Chlorination of indanthrone in sulfuric acid under addition of 1 % or 5 % manganese dioxide (5 – 8 % or 13.8 – 14 % Cl) at 50 – 55 °C affords

dyes of slightly greener shades (Indanthren Blue GCD or BC).

3,3′-Dichloro-4,4′-diaminoindanthrone [*1328-41-2*], Indanthren Green BB, (**112**), M_r 541.4, is prepared from 1,4-diamino-2,3-dichloroanthraquinone in naphthalene in the presence of copper powder [313].

112

Indanthrone-3,3′-dicarboxylic acid, Cibanone Blue 2 G, (**113**), M_r 530.4, is prepared from2-aminoanthraquinone-3-carboxylic acid by potash fusion [314].

113

Leuco-sulfuric ester of 3,3′-dichloroindanthrone [*2519-28-0*], Anthrasol Blue IBC, (**114**), M_r 839.7, is prepared from the leuco-sulfuric ester of 2-acetylamino-3-chloroanthraquinone [315].

114

2.12. Anthraquinone Derivatives with Meso Rings (1,9-Cyclo-10-anthrones)

This class includes anthraquinone derivatives that contain a condensed carbon or heterocyclic ring linking the α position and the neighboring meso position bridging the 1 and 9 positions. (These derivatives are named in the following discussion by their "traditional" nomenclature, which is still the one in common use in industrial dye circles. For example, the compound called benzanthrone in the "traditional" nomenclature would be named as 7-oxo-7*H*-benz [*d,e*]anthracene by the new nomenclature rules).

Such ring systems have been prepared in nearly every feasible combination, but only the few listed below have attained importance in the commercial synthesis of dyes.

Benzanthrone

Pyrazolanthrone

Anthrapyrimidine

N-Methylanthrapyridone

Without additional substituents, these compounds possess a relatively faint yellow color, and have a yellowish green fluorescence in organic solvents or sulfuric acid. This group also includes a number of polycyclic compounds with additional side and/or meso-ring systems, such as acedianthrone, anthanthrone (**145**, for formula see Section 2.12.6), pyranthrone (**149**, for formula see Section 2.12.7), violanthrone (**151**, for formula see Section 2.12.8), and dibenzpyrenequinone.

2.12.1. Benzanthrone and Its Derivatives

Benzanthrone is an important intermediate for the synthesis of vat dyes. It is prepared from anthrone (**122**), glycerol, and sulfuric acid under conditions similar to those employed in Skraup's quinoline synthesis. Industrial synthesis commonly starts directly from anthraquinone, which is first reduced to anthrone by an appropriate reducing agent (e.g., iron) without isolation of the intermediate.

Dyes of the basic benzanthrone system are of little importance. Commercial dyes are almost always benzanthrones with additional fused ring systems derived from benzanthrone and its simple substituted derivatives.

Benzanthrone is substituted easily. Electrophilic reagents usually attack the 3 position first and then the 9 position, whereas nucleophilic substitution attacks the 4 position or the 6 position. Therefore halogenation of benzanthrones first yields the 3-halo derivatives; more vigorous reaction conditions yield the 3,9-disubstituted compounds. Direct synthesis is used to generate derivatives bearing halogen in other positions and to obtain 4-methylbenzanthrone.

For halobenzanthrones, displacement reactions are carried out most easily with the halogen in positions 3 or 9. Condensation with aminoanthraquinone in inert solvents in the presence of acid-binding agents and a copper catalyst will yield condensation products of the anthrimide type. Valuable vat dyes, e.g., **116,** are derived by periring-closure of 3-(1-anthraquinonylamino)-benzanthrone (**115**) using a potash melt [316] or pyridine – aluminum chloride.

The bromine atoms of 3,9-dibromobenzanthrone can be replaced stepwise.

Pyrazolanthrones can be reacted with halobenzanthrones in a manner similar to 1-aminoanthraquinone [317].

115

116

117 **118**

3-Bromobenzanthrone reacts with sodium sulfide to yield the mercaptan, which may be alkylated with chloroacetic acid to give the thioglycolic acid derivative. This product may then be converted to an indigoid dye by oxidation and potash fusion [318]:

119

Treatment of 3-bromobenzanthrone with copper cyanide in an organic solvent yields 3-cyanobenzanthrone, which may be hydrolyzed to benzanthrone-3-carboxylic acid. This compound may then be converted further via the acid chloride and condensation with 1-aminoanthraquinone to the carboxamide (**120**), which in an alkali melt forms a ring by decarboxylation to give "Isoimide Green" (**121**) [319]:

120 **121**

Mild treatment of benzanthrone with alcoholic alkalies leads to dimerization, giving 4,4′-bibenzanthronyl (**129**), an important intermediate for the preparation of violanthrone dyes (see Section 2.12.8).

Benzanthrone [*82-05-3*], (**123**), M_r 230.3, *mp* 170 °C, is prepared commercially by reacting anthraquinone with glycerol, sulfuric acid, and a reducing agent, usually iron. This involves reduction of anthraquinone to anthrone (**122**), which condenses immediately with the acrolein formed by dehydration of glycerol, and is finally oxidized by the sulfuric acid [1], [2, p. 65], [320]. An improved process is described in [321], [322]. More recently, the use of phos-

phorus or a phosphorus compound, e.g., sodium hypophosphite, has been proposed as the reducing agent [323]. Electrochemical procedures have been also suggested [324], [325]. It is possible to start with anthrone prepared in a separate step, e.g., by hydrogenation [326]. Benzanthrone is best purified by sublimation.

122

123

4-Methylbenzanthrone [*6409-46-7*], (**124**), M_r 244.3, is prepared from 2-methylanthraquinone via methylanthrone with glycerol in sulfuric acid [327].

124

125

3-Bromobenzanthrone [*81-96-9*], (**125**), M_r 309.2, is prepared by bromination in hydrochloric acid [2, p. 71]; process improvement is described in [328].

3,9-Dibromobenzanthrone [*81-98-1*], (**126**), M_r 388.1, is prepared by bromination in chlorosulfonic acid [2, p. 76], [12], [329].

126

127

3-Cyanobenzanthrone, (**127**), M_r 255.3, is prepared from 3-bromobenzanthrone with CuCN in pyridine [330].

Benzanthrone-3-carboxylic acid, (**128**), M_r 274.3, is prepared from the nitrile by hydrolysis [331].

128

129

4,4′-Bibenzanthronyl [*116-90-5*], (**129**), M_r 458.5, is prepared by mild alcoholic alkali melt of benzanthrone (below 200 °C in the presence of excess alcohol) [1]. It is an intermediate in the synthesis of violanthrone dyes (see Section 2.12.8).

3-(1-Anthraquinonylamino)benzanthrone [*81-94-7*], (**115**), M_r 451.5, is prepared from 1-aminoanthraquinone and 3-halobenzanthrone [2, p. 71], [332].

Indanthren Olive Green B [*3271-76-9*], Imide Green, (**116**), M_r 449.5, is prepared from 3-(anthraquinonyl-(1)-amino)benzanthrone by alkali melt [2, p. 71], [316].

***N*-[Benzanthronyl-(3)]pyrazolanthrone** (**117**), M_r 448.5, is prepared from pyrazolanthrone and 3-bromobenzanthrone in nitrobenzene [317].

Indanthren Navy Blue R [*6247-39-8*], (**118**), M_r 466.5, is prepared from **117** by mild alkali fusion [317].

Additional compounds are given in the section on vat dyes, Section 3.1.3.

2.12.2. Pyrazolanthrone and Its Derivatives

1,9-Pyrazolanthrones are generated easily from the 1-hydrazinoanthraquinones [333] by ring closure with dehydration. This may be accomplished in either concentrated sulfuric acid at temperatures up to 100 °C or by heating in aqueous hydrochloric acid.

Hydrazinoanthraquinones are obtained from 1-aminoanthraquinones by diazotization, reduction with sodium hydrogen sulfite to the hydrazinosulfonic acid, and hydrochloric acid hydrolysis. Other synthesis options are displacement of halogen or sulfonic acid groups by hydrazine.

Only the unsubstituted pyrazolanthrone (**130**) is of commercial importance for the production of benzanthrone dyes obtained by reaction with 3-bromobenzanthrone and subsequent ring closure. It is also the starting material for the production of 2,2′-bipyrazolanthronyl (**131**). Alkylation of this substance then yields the corresponding diethyl derivative (Indanthren Rubin R, **132**).

130

1,9-Pyrazolanthrone [*129-56-6*], (**130**), M_r 220.2, *mp* 285 – 286 °C, is prepared by diazotization of 1-aminoanthraquinone, reaction of the diazonium salt with sodium hydrogen sulfite, and cyclization of the resulting hydrazinosulfonic acid [5, p. 160].

2,2′-Bipyrazolanthronyl [*129-54-4*], (**131**), M_r 438.5, is prepared from pyrazolanthrone in an alkali melt [13, p. 345], [334].

131

132

***N,N′*,-Diethyl-2,2′-bipyrazolanthronyl** [*4203-77-4*], (**132**), Indanthren Rubin R, M_r 494.6, is prepared from 2,2′-bipyrazolanthronyl by alkylation with diethyl sulfate after treatment with potassium hydroxide solution [5, p. 159]. For structure elucidation see [11, C.I. 70320].

2.12.3. 1,9-Anthrapyrimidine and Its Derivatives (1,9(*N*-)-Pyrimidinoanthrone-10)

The 1,9-anthrapyrimidines (**133**) are obtained easily from the corresponding 1-aminoanthraquinones by reaction with formamide [337] or with aqueous solutions of formaldehyde and ammonia in the presence of nitrobenzene sulfonic acid as the oxidizing agent [335], [336].

133

An equally smooth process starts by transforming 1-aminoanthraquinone into its formamidinium chloride by reaction with dimethylformamide and thionyl chloride, followed by ring closure in the presence of ammonium salts of weak acids [338]:

Only the 6- and 8-amino derivatives of 1,9-anthrapyrimidines are used as intermediates to produce greenish-yellow vat dyes. Unsubstituted 1,9-anthrapyrimidine is faint yellow, the 6-amino derivative is yellow with a green cast, and the 8-amino derivative is orange red.

6-Aminoanthrapyrimidine, (**134**), M_r 247.3, is prepared from 1,4-diaminoanthraquinone with aqueous formaldehyde and ammonia in the presence of nitrobenzenesulfonic acid [2, p. 88].

134

8-Aminoanthrapyrimidine, M_r 247.3, is prepared from 1,5-diaminoanthraquinone-2-sulfonic acid with aqueous formaldehyde and ammonia in the presence of nitrobenzenesulfonic acid, followed by splitting off the sulfonic acid group [2, p. 94]. In contrast to 1,4-diami-

noanthraquinone, reaction at only one side of the 1,5-diaminoanthraquinone is not assured.

6-(4′-Chlorobenzoylamino)anthrapyrimidine [*4216-00-6*], Indanthren Yellow 7 GK, M_r 385.8, is prepared by reacting 6-aminoanthrapyrimidine with 4-chlorobenzoyl chloride in *o*-dichlorobenzene [337] or from *N,N*-dimethyl-*N′*-[4-(4′-chlorobenzoylamino)anthraquinonyl-(1)] formamidinium chloride and ammonium acetate in *N*-methylpyrrolidone [338].

1,9-Anthrapyrimidine-2-carboxylic acid, (**135**), M_r 276.2, is prepared from 1-amino-2-methylanthraquinone with formamide or with formaldehyde–ammonia (addition of an oxidizing agent), followed by oxidation of the 2-methyl derivative to the 2-carboxylic acid [339].

135

Conversion into the acid chloride and condensation with aminoanthraquinone affords fast yellow vat dyes and pigments [340], [341].

2.12.4. 1,9-Anthrapyridone and Its Derivatives

1-Acetylaminoanthraquinones are converted to anthrapyridones by alkaline reagents [342] and by direct heating [343], which is accompanied by loss of water:

Acetylation and subsequent ring closure may also be combined by heating the aminoanthraquinone with acetic anhydride in the presence of alkali-metal acetates [344].

Only the 6-arylamino derivatives of 3-methylanthrapyridone and 1-ethoxycarbonyl-4methylanthrapyridone are of commercial interest. Starting from 4-bromo-1-methylaminoanthraquinone, the 6-bromo-3-methylanthrapyridone is obtained by acetylation and alkali-catalyzed ring closure [5, p. 217]. In this compound, the halogen may be easily displaced by amine functions [344]. Subsequent sulfonation yields lightfast red acid dyes (Alizarine Rubinoles).

6-Bromo-3-methylanthrapyridone, (**136**), M_r 340.2. For preparation see preceding paragraph [5, p. 217].

136

137

6-Anilino-3-methylanthrapyridone, M_r 352.4, is prepared from 6-bromo-3-methylanthrapyridone and aniline [3, p. 47].

6-Anilino-3-methylanthrapyridone-4′-sulfonic acid, (**138**), M_r 432.5, is prepared by condensation of 6-bromo-3-methylanthrapyridone with aniline, followed by monosulfonation [345].

138

139

1-Ethoxycarbonyl-6-bromo-4-methylanthrapyridone, (**139**), M_r 412.3, is prepared from 1-amino-4-bromo-2-methylanthraquinone and diethyl malonate [346].

2.12.5. Dibenzpyrenequinones

According to their chemical structure, dibenzpyrenequinones should be classified as benzanthrone derivatives, but conventionally they are treated as a separate group.

Although the yield of benzanthrone by dehydrogenating ring closure of 1-benzoylnaphthalene in an aerated aluminum chloride – sodium chloride melt is too low [13, pp. 315 – 317], these conditions are suitable for the double ring closure of 1,5- (or 1,4-) dibenzoylnaphthalene [348] to yield 7,14- (or 5,8-) dibenzpyrenequinone, (**141**), (**140**), [347].

The 7,14-dibenzpyrenequinone is used commercially as a golden-yellow vat dye. Another, now obsolete, method for preparing this compound is fusion of benzanthrone with benzoyl chloride and aluminum chloride [349] and, if necessary, with aeration with oxygen [350].

7,14-Dibenzpyrenequinone [*128-66-5*], Indanthren Golden Yellow GK (**141**), M_r 332.4, is prepared from 1,5-dibenzoylnaphthalene (itself prepared from naphthalene with benzoyl chloride – $AlCl_3$) by fusion with $AlCl_3$-NaCl at 160 °C and aeration with oxygen [5, p. 123], [347], [348].

Dibromo-7,14-dibenzpyrenequinone [*1324-11-4*], Indanthren Golden Yellow RK, M_r 490.2, is prepared by bromination in the melt [5, p. 121].

2.12.6. Anthanthrones

The intensely orange anthanthrone (**145**), which has little fiber affinity when used in its unsubstituted form as a vat dye, is produced by double ring closure of 1,1′-binaphthyl-8,8′-dicarboxylic acid (**144**) in sulfuric acid [351]. Anthanthrone is prepared commercially from naphthostyril (**142**), which is hydrolyzed to **143**, diazotized, and dimerized, losing N_2 [352].

In sulfuric acid, anthanthrone may be dichlorinated or dibrominated in the 4,10 positions. This procedure yields a dye with greater affinity and brighter, more intense red shades. In commercial processes halogenation is carried out immediately following the cyclization of **144**without isolation of intermediates.

4,10-Dichloroanthanthrone [*1324-02-3*], Indanthren Brilliant Orange GK, M_r 375.2, is prepared from 1,1′-binaphthyl-8,8′-dicarboxylic acid in sulfuric acid at 50 °C, followed by chlorination in the presence of $FeSO_4$ [5, p. 96], or from anthanthrone by sparging with chlorine in the presence of iodine in sulfuric acid or organic solvents [353].

4,10-Dibromoanthanthrone [*4378-61-4*], Indanthren Brilliant Orange RK, M_r 464.1, is prepared from 1,1′-binaphthyl-8,8′-dicarboxylic acid in sulfuric acid monohydrate at 35 °C, followed by bromination in the presence of iodine [5, p. 88]. It is also used as a pigment.

4,10-Bis-(4′-benzoylaminoanthraquinonyl-1′-amino)anthanthrone [*6049-19-0*], Indanthren Grey BG, (**146**), M_r 987.0, is prepared from 4,10-dibromoanthanthrone and 1-amino-4-benzoylaminoanthraquinone in naphthalene [354].

2.12.7. Pyranthrone and Flavanthrone

Pyranthrone [*128-70-1*], (**149**), M_r 406.4, is prepared by double ring closure of 2,2′-dimethyl-1,1′-bianthraquinonyl (**148**), which is obtained from 1-chloro-2-methylanthraquinone (**147**) by heating with copper powder in *o*-dichlorobenzene – pyridine. Ring closure occurs under alkaline conditions, e.g., KOH – isobutanol at 105 °C [2, p. 60]; process improvements are reported in [355], [356]. The unsubstituted pyranthrone and its halogen derivatives are used as vat dyes and pigments.

Brominated pyranthrones (the dibromo derivative [*1324-35-2*], M_r 564.3, is Indanthren Orange RRTS [2, p. 61]; a mixture of di- and tribromo derivatives is Indanthren Orange 4 R [2, p. 62]) are prepared from pyranthrone by bromination in chlorosulfonic acid in the presence of iodine or sulfur.

Flavanthrone [*475-71-8*], (**150**), M_r 408.4. Strictly speaking, flavanthrone should not be classified with the polycarbocyclic anthraquinone derivatives, but it is described here because it is so similar to pyranthrone.

Flavanthrone is prepared from 1-chloro-2-phthalimidoanthraquinone via the 2,2′-diphthalimido-1,1′-bianthraquinonyl, using copper in boiling trichlorobenzene. The alkaline ring closure is accomplished by boiling with excess 3 – 5 % sodium hydroxide, which cleaves both phthalic acid residues simultaneously [5, p. 174]. Only the unsubstituted flavanthrone is used as a vat dye and pigment.

2.12.8. Violanthrone and Isoviolanthrone

Both violanthrone (**151**) and isoviolanthrone (**152**) are formally derived by symmetrical or unsymmetrical condensation of two molecules of benzanthrone. Both polycyclic quinones have intense blue color and are used either by themselves or in the form of simple derivatives as fast violet to green or black vat dyes and as pigments. In contrast to isoviolanthrone, unsubstituted violanthrone is available as a commercial dye.

Violanthrone may be brominated or chlorinated in chlorosulfonic acid or organic solvents. Both reactions are used to obtain other hues. If sulfur is added during halogenation in chlorosulfonic acid, derivatives containing sulfur and halogen are obtained.

Nitration of violanthrone yields a mixture of mono- and dinitroviolanthrones, which are reduced in the vat dyeing process to (di)aminoviolanthrones.

Alternatively, reduction of the nitro group may be carried out during the original dye synthesis.

Posttreatment of the resulting greenish fabric color with an oxidizing agent, such as hypochlorite, produces fast, deep black colors.

Violanthrone [*116-71-2*], Indanthren Dark Blue BOA, (**151**), M_r 456.5, is generated by potash fusion of benzanthrone [11], [2, p. 75].

Direct potash fusion leads to side products, such as isoviolanthrone and 4-hydroxybenzanthrone. The crude product may be used directly or in mixtures with other dyes in vat dyeing. It is also used to generate violanthrone derivatives. Several processes have been developed to decrease the amounts of undesirable side products of the direct potash fusion of benzanthrone or to purify the bibenzanthronyl or the crude violanthrone [357–359]. Especially effective is the addition of high-boiling solvents such as naphthalene, the so-called low carbazole anthracene residues, or sodium acetate to the melt. The quality of the products prepared by these methods is satisfactory for the production of almost all violanthrone dyes.

Violanthrone of high purity is obtained from 4,4′-bibenzanthronyl (**153**) by alkaline or acid ring closure, preferably in the presence of oxidizing agents [359], [360]. If this ring closure is carried out in sulfuric acid with an excess of manganese dioxide, the 16,17-violanthronequinone (**155**) is obtained. This can be reduced readily with sodium hydrogen sulfite to 16,17-dihydroxyviolanthrone (**156**). Subsequent alkylation of the hydroxy groups yields very fast navy-blue to brilliant-green vat dyes. The dimethyl ether (**157**) is the well-known dye Caledon Jade Green or Indanthren Brilliant Green B and FFB (extremely pure form).

3,12,16,17-Tetrachloroviolanthrone [*84617-19-6*], Indanthren Navy Blue RB, M_r 594.3, is prepared by chlorination in trichlorobenzene [4, p. 27].

Bromoviolanthrones, with one bromine atom (Indanthren Navy Blue BRF, M_r 535.4) or with two bromine atoms (Indanthren Navy Blue BF [*1328-18-3*], M_r 614.3), are prepared by bromination of violanthrone in chlorosulfonic acid in the presence of sulfur [361] or antimony [362].

Nitroviolanthrone [*57455-91-1*], Indanthren Black BB, M_r 501.5, is prepared by nitration of violanthrone [363].

16,17-Dimethoxyviolanthrone [*128-58-5*], Indanthren Brilliant Green FFB, Caledon Jade Green, (**157**), M_r 516.6, is prepared from 4,4′-bibenzanthronyl by ring closure and oxidation followed by reduction and ether formation [1], [5, p. 81], [364].

Isoviolanthrone [*128-64-3*], (**152**), M_r 456.5. Formerly prepared from 3-halobenzanthrone by alcoholic potash melt. Isomer-free isoviolanthrone is obtained by an alcoholic potash melt of 3,3′-dibenzanthronyl sulfide [365] or by the one-pot method [366].

Dichlorination of isoviolanthrone with sulfuryl chloride, or alternatively bromination in chlorosulfonic acid, affords brilliant violet vat dyes and pigments.

Dichloroisoviolanthrone [*1324-55-6*], (Indanthren Brilliant Violet RR and 4 R with chlorine in the 6,15 positions), M_r 524.4, is prepared from isoviolanthrone by chlorination with sulfuryl chloride [367].

Tribromoisoviolanthrone [*1324-17-0*], Indanthren Brilliant Violet 3 B and F 3 B, M_r 693.2, is prepared by bromination of isoviolanthrone in chlorosulfonic acid in the presence of sulfur [4, p. 9].

2.12.9. Acedianthrone

The unusual ring system of acedianthrone [*129-68-0*], (**158**), is generated from anthrone by condensation with glyoxal sulfate [368], followed by alkaline oxidation of the glyoxal anthrone [368] and subsequent ring closure catalyzed by sulfuric acid, or by direct fusion of the glyoxal anthrone with $AlCl_3$-NaCl [369], [370].

158

This process has found industrial application in the production of the dichloro compound from 2-chloro-9-anthrone.

Dichloroacedianthrone [*6424-51-7*], Indanthren Red Brown RR, (**159**), M_r 475.3, is prepared from 2-chloroanthrone and glyoxal sulfate in chlorobenzene via 2,2′-dichloroanthroneethylene, followed by ring closure in sulfuric acid [4, p. 47], [5, p. 149].

159

3. Dye Classes

The introduction of auxochromes into the almost colorless anthraquinone permits the tailoring of compounds to cover nearly all shades of dye colors: types and positions of the substituents in the molecule determine the hue. As a rule the bathochromic shift in simple anthraquinones increases with increasing basicity of the substituents. This generalization is clearly shown by the wavelengths of the longest wavelength absorption maximum of anthraquinones monosubstituted in the 1-position [371]:

Subst.	λ [mμ]
H	327
Cl	337
OCH_3	380
OH	405
$NHCOCH_3$	410
$NHCOC_6H_5$	415
SCH_3	438
NH_2	465
$N(CH_3)_2$	504
$NHCH_3$	508
NHC_6H_5	508

The wavelengths of the absorption maxima of hydroxy- and aminoanthraquinones are a function of position and number of OH and NH_2 groups [371]:

Position:	2	1	1,2	1,5	1,8	1,4
OH λ [mμ]	365	405	416	428	430	476
NH_2 λ [mμ]	410	465	480	480	492	550

The large shift from the 1,8- to the 1,4-disubstituted anthraquinones, which even exceeds that between the α- and the β-substituted compounds, is remarkable. For α-substituents, additional changes in shade and color fastness occur on formation of hydrogen bonds to the neighboring carbonyl group.

Alteration of color in isomeric compounds can be demonstrated by comparing various diaminohydroxyanthraquinones:

The effect of β-substituents on the hue is best demonstrated by the 1,4-diaminoanthraquinones:

R = OCH_3, Red Violet
= OC_6H_5, Slightly Red Violet
= H, Violet
= $SO_2OC_6H_5$, Red Blue
= $COOCH_3$, Slightly Red Blue
= NO_2, Blue Green

Furthermore, the shade may be modified strongly by ring closure and condensation reactions:

Yellow Brown Olive Green

Not every colored anthraquinone derivative is a dye. In addition to tinctorial strength and depending on the intended use, such other properties as affinity to the fiber and resistance to atmospheric conditions must be present also. The choice of a particular textile dye is determined also by its application properties and its fastness.

The three major dye types, i.e., neutral, anionic, and cationic dyes, are subdivided by use.

Neutral dyes: disperse dyes, vat dyes, pigments, and dyes soluble in organic solvents.
Anionic dyes: acid dyes, direct dyes, and reactive dyes.
Cationic dyes: dyes for polyacrylonitrile fibers and other fibers modified to contain acid groups.

The Colour Index (C.I.) numbers given for the individual dyes in the following sections correspond to the numbering system of the Colour Index [11] where additional references can be found.

3.1. Neutral Dyes

3.1.1. Disperse Dyes

The disperse dyes are water-insoluble, colloidally dispersed materials that are used to dye synthetics, including polyester, polyamide, and acetate fibers having 2.5 or 3 acetate groups per glucose subunit. Disperse dyes are used for dyeing polyacrylonitrile fibers when good leveling of light shades is required. Although disperse dyes were developed many decades ago for coloring cellulose acetate fibers, the most important application is to dye polyester fibers.

The simple anthraquinone dyes, containing hydroxy or amino functions as their major auxochromes, are used for brilliant red to blue shades. Yellow and orange shades are obtained by other dye classes. Choosing appropriate substituents allows the best dyes for various fibers and colors to be obtained.

3.1.1.1. Dyes for Polyester Fibers

Anthraquinone dyes for polyester fibers can be classified into five basic types:

Yellow Red to Rubine | Violet to Blue Green | Red Blue to Blue

1 X = NH_2, 2 X = OH Blue to Green Blue | 1 X = OH, 1 X = NO_2 Green Blue

The most important factors in the selection of anthraquinone dyes are affinity, light fastness, and resistance to sublimation. Large substituents

in the side chain tend to improve the sublimation fastness considerably. On the other hand, increased sublimation resistance generally decreases the affinity characteristics of the dye. The affinity is greatly affected by the position and the hydrophilic characteristics of the substituents. Mixtures of appropriate dyes or the presence of contaminants formed during synthesis may increase affinity by synergistic action. Introduction of negatively charged substituents, for instance, carboxylic esters, halogen, or sulfone groups, may improve light fastness.

1-Amino-4-hydroxyanthraquinones (for preparation see page 19) possess good light fastness and affinity for polyester fibers. They are bright, red dyes, whose brilliance may be improved significantly by introduction of ether groups ortho to the amino groups. The aliphatic ethers surpass the aromatic ethers with respect to light fastness and are much more yellow and somewhat brighter. Additional substituents in the side chains may improve sublimation resistance. Isomeric compounds with alkyl or aryl ether groups in addition to hydroxyl entities are of little commercial interest because their shades are more blue and duller.

Examples are **160** and **161** both bright yellow reds [372], [373]; **162**, bright blue red (R = H: C.I. Disperse Red 60, C.I. 60756 [*17418-58-5*], e.g., Resolin Red FB, Bayer); for **b** see [374]; for **c** see [375].

161 Bright Yellow Red

162 Bright Blue Red

a R = H

b R = 
c R = 
1,4-Diaminoanthraquinones (for preparation see page 9). The poor light fastness of 1,4-diaminoanthraquinone can be improved by appropriate negatively charged substitutents. The 2-sulfophenyl ester is a sublimation-resistant, brilliant blue dye with a reddish cast and good light fastness. The introduction of a nitro group into the 2 position shifts the shade into bluish green and improves resistance to sublimation and fading. Introduction of chlorine atoms into the β position considerably improves light fastness with little affect on the basic sublimation characteristics.

β-Phenoxy groups in the 2,3 positions shift the shade to a bright, somewhat reddish violet with good stability to fading and sublimation. A very bright turquoise color with excellent light fastness and good resistance to sublimation are properties of the 2,3-dicarboximides.

Examples are **167a**, C.I. Disperse Violet 28, 61102 [*81-42-5*] (e.g. Resolin Violet RL, Bayer); **163b**, a red violet dye [3, p. 48]; **164a**, blue green [376]; **167b** brilliant red blue [377]. Compounds **165** and **166** are both turquoise blue dyes [378], [379].

166 Turquoise Blue

***N*-Substituted 4-Amino-1-hydroxyanthraquinones.** Alkyl- (or aryl-) aminohydroxyanthraquinones, which show good affinity and light fastness and give violet to blue shades, generally do not satisfy the requirements with

respect to sublimation fastness. Compared to the dyes of the tetrasubstituted series, they are of lower tinctorial strength. Such substituents as carboxylic esters, arylsulfonic esters, amides, hydroxyethylether, and methoxy groups in arylamino compounds improve sublimation resistance, whereas optimized blends prevent lowering of affinity.

Examples are **167a**, C.I. Disperse Violet 27, 60724 [*19286-75-0*]; **167b**, C.I. Disperse Blue 72, 60725 [*81-48-1*], and **167c**, a violet dye [380].

167

a R = H C.I. Disperse Blue 27
b R = CH_3 C.I. Disperse Blue 72
c R = $O{-}SO_2CH_3$ Violet

Diaminodihydroxyanthraquinones (for preparation see page 24). Derivatives of α-diaminodihydroxyanthraquinones are the most important disperse dyes with respect to shade and affinity. The dye properties may be optimized by introducing suitable substituents, selecting the positions of the isomers, and blending. Some of these properties can be illustrated with the three basic structures shown below:

168 **169** **170**

The bathochromic shift from **168** to **170** affects the color; the light fastness increases in the order of **169** → **170** → **168**; and the affinity increases from **168** → **170** → **169**. The sublimation fastness of all three is moderate.

Halo, alkoxy, hydroxyaryl, and phenylmercapto derivatives have attained commercial importance. Compared to substitution next to the hydroxy group, substitution next to the amino group leads to brighter dyes and improved affinity.

Examples are **171**, C.I. Disperse Blue 56, 63285 [*12217-79-7*] (e.g., Resolin Blue FBL, Bayer) and **172,** C.I. Disperse Blue 73, 63265 [*12222-75-2*].

171 C.I. Disperse Blue 56

172 C.I. Disperse Blue 73
R = H, CH_3

Nitroarylaminodihydroxyanthraquinones. These dyes are valued because of their greenish-blue shade and their good fastness to light and sublimation. Reduction improves their affinity somewhat but decreases light fastness.

Example : **173** is a blue dye of this kind [381].

173 Blue

3.1.1.2. Dyes for Cellulose Ester and Synthetic Polyamide Fibers

The first disperse dyes (Celliton) were developed for dyeing cellulose fibers, but the importance of these diminished considerably when other synthetic fibers appeared on the market. Synthetic polyamide fibers could be dyed with dyes used for acetate fibers: very few new dyes had to be developed specifically for polyamide fibers.

The basic type of dye closely resembles that used for dyeing polyester fibers, but the selection of compounds is based on other criteria. Requirements regarding sublimation resistance are not as stringent, whereas fastness to ozone, exhaust gases, and washing are important. Substitution by amino, and especially by alkylamino, groups tends to decrease light fastness of the dyes in polyester fibers. This is not the case for acetate and polyamide fibers.

The orange derivatives of 1-aminoanthraquinone are of little importance in this context because of their low tinctorial strength. This contrasts with the 1-amino-4-hydroxyanthraquinone derivatives, which provide brilliant red dyes. The most important are dyes derived from 1,4-diaminoanthraquinone, with shades ranging

from violet to greenish blue. Affinity may be enhanced vastly by blending similar compounds.

Examples of this class of dyes are **174,** a brilliant red dye [382]; **175,** C.I. Disperse Blue 14, 61500 [*2475-44-7*] [3, p. 54] (e.g., Celliton Fast Blue, BASF); **176,** a brillant blue dye [383]; **177,** C.I. Disperse Blue 31, 64505 [*1328-23-0*] [3, p. 53] (e.g., Celliton Blue 3 G, BASF); **178,** C.I. Disperse Blue 7, 62500 [*3179-90-6*] [5, p. 201] (e.g., Celliton Blue Green B, BASF).

178 C.I. Disperse Blue 7

3.1.1.3. Transfer Dyes

In transfer printing the dye is supplied in the form of a coating on transfer paper. The fabric is pressed closely against the paper, and the dye is sublimed at ≈ 200 °C and diffuses into fibers. This process is used primarily for printing on polyester fabrics. Originally it relied on available disperse dyes with good sublimation characteristics. Dyes, specifically developed for this process have also appeared on the market (see also [6, vol. VIII, pp. 191 ff.]).

Examples are **179,** C.I. Disperse Red 60, 60756 [*17418-58-5*], and **180,** C.I. Disperse Blue 26, 63305 [*3860-63-7*].

179 Disperse Red 60

180 Disperse Blue 26

3.1.1.4. Dyes for Cotton – Polyester Fabrics

Anthraquinone dyes of medium molecular mass are suitable for direct printing and dyeing of cellulose fibers, especially cotton – polyester fabrics pretreated with water. Most of these dyes are classified as disperse dyes having excellent resistance to sublimation, but vat dyes of low molecular mass are included also. The dyes are applied generally together with higher boiling, water-miscible solvents (glycol and glycol derivatives [384] or boric acid esters of species with one to six hydroxy groups [385]) to fabrics preswollen with water. Heat treatment at ≈ 200 °C evaporates the water, and the dye enters the fiber via its solution phase. The polyester component of the fabric is dyed simultaneously.

Examples: Compounds **181** [384] and **182** [386] are blue dyes; **183** [387] is green.

181 Blue

182 Blue

183 Green

Reactive disperse dyes also make it possible to dye cotton–polyester fabrics in equal shades. Fluorotriazine reactive dyes have been proposed for this application [388–390].

Examples: Compound **184** [388] is a blue, and **185** [389] a red dye.

184 Blue

185 Red

3.1.2. Dyes Soluble in Organic Solvents

Anthraquinone dyes of relatively simple structure are used for coloring gasoline, oil, and plastics. For example, the highly soluble bis(alkylamino)anthraquinones are suitable additives for gasoline, whereas quinizarin and its derivatives are used for marking heating oils. Note: addition of alkali causes a color change.

Examples: Compound **186** is a blue dye for the coloring of hydrocarbons, including gasoline [391]. Compound **187** is a mixture of blue dyes used to color gasoline and mineral oils [392].

186 Blue

187 Blue

Dyeing of amorphous thermoplastics – polymethacrylate, (modified) polystyrene, or polycarbonate – requires dyes soluble in these materials so that transparency can be retained. However, such dyes also are used in combination with titanium dioxide or other materials to provide body colors for the thermoplastics. Initially compounds with relatively simple structures were used, many of them drawn from stocks of existing intermediates. Since then new products designed to satisfy the specific requirements have become available.

Examples are **188**, C.I. Solvent Red 111, 60505 [*82-38-2*]; **189**, C.I. Solvent Red 52, 68210 [*81-39-0*]; **190**, C.I. Solvent Violet 13, 60725 [*81-48-1*]; **191**, C.I. Solvent Green 3, 61565 [*128-80-3*].

188 C.I. Solvent Red 111

190 C.I. Solvent Violet 13

191 C.I. Solvent Green 3

Many relatively simple amino- and hydroxyanthraquinone derivatives show a high degree of order in liquid crystalline systems and are therefore suitable as dichroic dyes for guest – host displays. Several new dyes for this application have been described.

Example: Compound **192** is a blue dichroic dye [393].

192 Blue

3.1.3. Vat Dyes

Vat dyes have been used for many decades to color cotton and other cellulose fibers. Despite their high cost and their muted colors, these dyes are extremely important for certain textiles because of their superior fastness. Very few new vat dyes have been developed over the past few years.

Water-insoluble vat dyes are converted to soluble "anthrahydroquinones" by reducing agents, such as sodium dithionite (hydrosulfite) in the presence of sodium hydroxide. The sodium salts of these mostly deep colored leuco compounds penetrate cellulose fibers. The insoluble dye is attached firmly to the fiber after reoxidation (→ Textile Dyeing). Representative of a special form are the water-soluble sulfuric acid es-

ters of the "anthrahydroquinone" compounds (→ Leuco Esters of Vat Dyes).

On the basis of their chemical constitutions the anthraquinoid vat dyes may be classified in the following major groups:

acylaminoanthraquinones
anthraquinoneazoles
anthrimides and other linked anthraquinones
anthrimidocarbazoles
phthaloylacridones
benzanthrone dyes
indanthrones
other polycondensed ring systems

Acylaminoanthraquinones. Acylation of aminoanthraquinones with benzoic acid or benzoyl chloride, for example, affords vat dyes with satisfactory affinity for cellulose fibers. The simplest dyes of this type, 1,4- (and 1,5-) dibenzoylaminoanthraquinones, are no longer important. Bridging linkages, such as the dicarboxylic acids oxalic or phthalic acid, permit coupling of two anthraquinone units; three aminoanthraquinones may be combined by use of a triazine, such as cyanuric chloride.

Acylation of 1-amino- (or 1,5-diamino) anthraquinones yields yellow vat dyes and affords red to ruby colored dyes when 1,4-diaminoanthraquinones are used. Use of 4,8-diamino-1,5-dihydroxyanthraquinones gives violet to blue dyes. The relatively low light fastness of the yellow acylaminoanthraquinones may be improved greatly by using azodiphenyl-4,4′-dicarboxylic acid. All acylaminoanthraquinones are relatively sensitive to atmospheric conditions, except the yellow acylation product obtained from anthrapyrimidinecarboxylic acid and 1-aminoanthraquinone.

Examples of this class of dyes are **193**, C.I. Vat Violet 15, 63355 [*6370-58-7*] [4, p. 8] (e.g., Indanthren Brilliant Violet BBK, Bayer); **194** C.I. Vat Yellow 12, 65405 [*6370-75-8*] [4, p. 56] (e.g., Indanthren Yellow 3 GF, Bayer); **195**, C.I. Vat Orange 17, 65415 [*6370-77-0*] [394] (e.g., Indanthren Orange GG, Bayer); **196**, C.I. Vat Yellow 10, 65430 [*2379-76-2*] [5, p. 178] (e.g., Indanthren Yellow GGF, Cassella); **197**, C.I. Vat Yellow 20, 68420 [*4216-01-7*] [395] (e.g., Indanthren Yellow 4 GF, BASF); **198**, C.I. Vat Red 28, 65710 [*6370-82-7*] [10, p. 353] (e.g., Cibanone Red G, Ciba-Geigy).

195 C.I. Vat Orange 17

196 C.I. Vat Yellow 10

197 C.I. Vat Yellow 20

198 C.I. Vat Red 28

Anthraquinoneazoles. In contrast to the older yellow Algol dyes, which contain two thiazole rings (see page 32), the red to blue oxazoles and thiazoles derived from 1-aminoanthraquinone-2-carboxylic acid and 3-amino-2-hydroxy- (or -mercapto-) anthraquinones exhibit good light fastness. The good fastness to atmospheric conditions and chlorine of the blue derivatives of 1-amino-4-aroylaminoanthraquinone-2-carboxylic acid deserves special mention.

Examples are **199**, C.I. Vat Red 10, 67000 [*2379-79-5*] [5, p. 152] (e.g., Indanthren Red FBB, BASF); **200**, C.I. Vat Blue 30, 67110 [*6492-78-0*] [2, p. 17], [5, p. 72] (e.g., Indanthren Blue CLB, BASF).

199 C.I. Vat Red 10

200 C.I. Vat Blue 30

Anthrimides and Other Linked Anthraquinones. Among the anthrimides (dianthraquinonylamines), only the α,β derivatives have reached a limited importance as vat dyes. Coupling two anthraquinone molecules via functional derivatives of the 2-aldehyde (or 2-carboxy) group offers another type of building block for vat dyes. Such compounds, e.g., 1-aminoanthraquinones, are linked in the 2 position via an azine or oxadiazole group, and all have good fastness.

Examples are **201**, C.I. Vat Violet 16, 65020 [*4003-36-5*] [4, p. 14] (e.g., Indanthren Corinth RK, Bayer); **202**, C.I. Vat Red 18, 60705 [*6409-68-3*] [2, p. 64] (e.g., Indanthren Bordeaux B, BASF); **203**, C.I. Vat Blue 64, 66730 [*15935-52-1*] [396] (e.g., Indanthren Blue ER, Bayer); **204**, C.I. Vat Red 13, 70320 [*4203-77-4*] [5, p. 159] (e.g., Indanthren Rubine R, Cassella).

203 C.I. Vat Blue 64

204 C.I. Vat Red 13

Anthrimide Carbazoles. Fast vat dyes are produced by carbazole ring closure from α,α-dianthraquinonylamines (anthrimides). The shade is determined by the number and position of the carbazole systems and by additional substituents, especially acylamino or alkoxy groups. Anthraquinone carbazoles make it possible to dye cellulose fibers in level, very fast yellow, orange, brown, gray, and olive shades. However, this series lacks dyes with bright shades.

Examples include **205**, C.I. Vat Yellow 28, 69000 [*4229-15-6*] [4, p. 53] (e.g., Indanthren Yellow FFRK, Hoechst); **206**, C.I. Vat Orange 15, 69025 [*2379-78-4*] [4, p. 15], [5, p. 119] (e.g., Indanthren Golden Orange 3 G, Bayer); **207**, C.I. Vat Brown 3, 69015 [*131-92-0*] [4, p. 10] (e.g., Indanthren Brown FFR, Bayer); **208**, C.I. Vat Black 27, 69005 [*2379-81-9*] [4, p. 29], [5, p. 135] (e.g., Indanthren Olive R, Bayer); **209**, C.I. Vat Brown 1, 70800 [*2475-33-4*] [5, p. 101] (e.g., Indanthren Brown BR, Bayer); **210**, C.I. Vat Green 8, 71050 [*14999-97-4*] [4,

p. 23] [5, p. 129] (e.g., Indanthren Khaki GG, Hoechst).

207 C.I. Vat Brown 3

208 C.I. Vat Black 27

209 C.I. Vat Brown 1 **210** C.I. Vat Green 8

Phthaloylacridones. Depending on the substituent in the 2 position, the 3,4-phthaloylacridones supply shades varying between red and green. The acridone vat dyes combine good light fastness with somewhat poorer wash fastness. Dyes of this series are especially suited for printing purposes because of the ease of vatting.

Examples are **211**, C.I. Vat Blue 21, 67920 [*6219-97-2*] [4, p. 34], [5, p. 143] (e.g., Indanthren Blue HCGK, Hoechst); **212**, C.I. Vat Green 12, 70700 [*6661-46-7*] [4, p. 19].

211 C.I. Vat Blue 21

212 C.I. Vat Green 12

Benzanthrone Dyes. Vat dyes derived from benzanthrone can be subdivided into two major groups: the peri ring-closure products of 3-anthraquinonylaminobenzanthrone, referred to as 'imide-green' dyes, and the dyes of the violanthrone and the isoviolanthrone series.

The first class gives the muted colors olive green, olive, khaki, and grey and excels in its resistance to light and atmospheric conditions. The blue color of violanthrone is shifted to a brilliant green by introducing two alkoxy groups into the 16 and 17 positions. An additional shift may be achieved by halogenation.

A redder and brighter shade is obtained with isoviolanthrone. Its halogenation products are marketed as brilliant violet dyes. Related to violanthrone is the alkaline ring closure product of the 3-pyrazolanthronylbenzanthrone, which is used as a navy blue vat dye.

Examples are **213**, C.I. Vat Green 3, 69500 [*3271-76-9*] [2, p. 71] (e.g., Indanthren Olive Green B, BASF); **214**, C.I. Vat Black 25, 69525 [*4395-53-3*] [2, p. 76] (e.g., Indanthren Olive T, BASF); **215**, C.I. Vat Blue 25, 70500 [*6247-39-8*] [4, p. 26] (e.g., Indanthren Navy Blue R, Hoechst); **216**, C.I. Vat Blue 20, 59800 [*116-71-2*] [5, p. 108] (e.g., Indanthren Dark Blue BOA, BASF); **217**, C.I. Vat Green 1, 59825 [*128-58-5*] [2, p. 69], [5, p. 83] (e.g., Indanthren Brilliant Green FFB, BASF); **218**, C.I. Vat Violet 1, 60010 [*1324-55-6*] [367] (e.g., Indanthren

Brilliant Violet RR, BASF); **219**, C.I. Vat Blue 26, 60015 [*4430-55-1*] [414] (e.g., Indanthren Cyanine B, BASF).

218 C.I. Vat Violet 1

219 C.I. Vat Blue 26

Indanthrones. The blue indanthrone was the first synthetic vat dye of the anthraquinone series. Because of its excellent fastness and bright colors it has remained the most important vat dye for a long time despite its low resistance to chlorine. Its chlorine resistance can be improved somewhat by post-halogenation. Introduction of hydroxy or amino groups shifts the shade to green.

Examples are **220**, C.I. Vat Blue 4, 69800 [*81-77-6*] [2, p. 52], [5, p. 73] (e.g., Indanthren Blue RS, BASF); **221**, C.I. Vat Green 11, 69850 [*1328-41-2*] [4, p. 18] (e.g., Indanthren Green BB, Bayer).

220 C.I. Vat Blue 4

221 C.I. Vat Green 11

Highly Condensed Ring Systems. A valuable supplement to the anthraquinone vat dyes is found in the more highly condensed carbocyclic quinones dibenzpyrenequinone, anthanthrone, and pyranthrone. These substances are yellow to red vat dyes without additional auxochromic substituents. Halogenation may improve their substantivity and change their shades. The halo derivatives can be converted to anthrimide-like compounds by reaction with aminoanthraquinones. These are in themselves useful as vat dyes and dye cotton in brown to grey shades but can be subjected to further carbazolyation.

Examples are **222**, C.I. Vat Orange 1, 59105 [*1324-11-4*] [2, pp. 117, 119] (e.g., Indanthren Golden Yellow RK, Hoechst); **223**, C.I. 3.1.4. Pigments

Because of their low solubility in organic media, most vat dyes should also be usable as pigments. However, for this type of use they must be prepared with a high degree of purity and with special physical properties (crystal modification, particle size distribution, etc.). The relatively high costs of synthesizing anthraquinone pigments restrict their use to special applications where requirements for fastness are stringent. Only a few of the known vat dyes satisfy these requirements. Apart from some acylaminoanthraquinones, mostly dyes with polycondensed ring systems, including indanthrones, anthanthrones, pyranthrones, flavanthrone, and their halogen derivatives, have some importance as pigments. Beyond that a number of spe-

cialty anthraquinone dyes have been developed as pigments over the past 25 years: for example, anthraquinone-azo, bianthraquinonyl, and anthraquinonylaminotriazine derivatives.

Only of little interest at present are the colored lakes, especially aluminum lakes of the hydroxyanthraquinones, such as alizarine, purpurin, and quinizarin and their sulfonic acids. (For preparation see Chap. 2; for formulation and application → Pigments, Organic, and [398].)

Examples are, **228** C.I. Pigment Yellow 108, 68420 [*4216-01-7*]; **229** C.I. Pigment Blue 60, 69800 [*81-77-6*]; **230** C.I. Pigment Red 168, 59300 [*4378-61-4*]; **231** C.I. Pigment Orange 40, 59700 [*128-70-1*]; **231** C.I. Pigment Yellow 24, 70600 [*475-71-8*]; **233**, yellow pigment [399]; **234**, C.I. Pigment Red 177, 65300 [*4051-63-2*]; **235**, yellow pigment [400]; **236** Aluminum Lake, C.I. Pigment Violet 5 : 1; 58055 : 1 [*145-48-2*].

3.2. Anionic Dyes

The anionic anthraquinone dyes may be classified by type of application and dyeing procedure into the following groups:

acid dyes
direct dyes
reactive dyes

3.2.1. Acid Dyes

Acid dyes are used for dyeing wool, synthetic polyamides, and silk in aqueous media. They may be subdivided into the following basic types:

The majority of the acid anthraquinone dyes available commercially give bright blue shades not obtainable with azo dyes. The red and yellow anthraquinone dyes are of little importance. Dyes of green shades obtained by combining yellow and blue dyes possess mostly slight wash fastness. Here, the uniformly dyeing green dyes of the anthraquinone series have proved their special value. The acid anthraquinone dyes are classified for particular applications according to their leveling characteristics, light fastness, and wash fastness. Once synthetic polyamide fibers were introduced in the market appropriate types were selected from the existing stocks. Special acid dyes have been developed for polyamides.

1-Aminoanthraquinone-2-sulfonic Acids. Condensation of bromamine acid (1-amino-4-bromoanthraquinone-2-sulfonic acid, see page 16) with aromatic or cycloaliphatic amines is used to produce a large number of blue acid dyes. The shade, leveling characteristics, wash fastness, and light fastness may be varied over a wide range by choosing particular amines. Cycloaliphatic amines provide the same brightness as aliphatic dyes but impart greater light fastness. Arylamines substituted with alkyl, halogen, aryl, aryloxy, or sulfonic ester groups yield dyes with better wash fastness and affinity in neutral media but less uniform leveling. Substituents at the *o* position cause a hypochromic shift and increase brilliance.

The arylamino residue may be altered subsequently by sulfonation, halogenation, acylation, or by the Einhorn reaction. Substitution of anthraquinone in the 5, 6, 7, or 8 positions offers an additional possibility to change the characteristics of the dye. For instance, halogen atoms and sulfonic acid groups cause bathochromic effects that are most pronounced when the substituents are introduced in the β position. The solubility of the 2,6- (or 2,7-) disulfonic acids is higher than that of the 2,5- (or 2,8-) series.

Examples are **237,** C.I. Acid Blue 25, 62055 [*6408-78-2*] [3, p. 41] (e.g., Acilan Direct Blue A, Bayer); **238,** C.I. Acid Blue 62, 62045 [*4368-56-3*] [3, p. 30] (e.g., Alizarine Brilliant Blue R, Bayer); **239,** C.I. Acid Blue 129, 62058 [*6397-02-0*] [401]; **240,** C.I. Acid Blue 40,

62125 [*6424-85-7*] [2, p. 135] (e.g., Anthralan Blue G, Hoechst); **241** [402] and **242** [404] are brilliant blue dyes.

Diaminodihydroxyanthraquinonesulfonic Acids. These dyes belong to the oldest synthetic acid wool dyes, but their importance has decreased considerably. An example for this class is **243,** C.I. Acid Blue 43, 63000 [*2150-60-9*] [3, p. 42] (e.g., Acilan Saphirol SE, Bayer).

242 Brilliant Blue

243 C.I. Acid Blue 43

1,4-Diaminoanthraquinones with External Sulfonic Acid Groups. A common feature of dyes of this group is their manufacture by sulfonation of the corresponding dye base derived from quinizarin or haloaminoanthraquinones. The reaction products of quinizarin with aromatic or araliphatic amines predominate in number and importance. The introduction of hydroxy groups into the 5 or the 5,8 positions brings about the expected bathochromic shift. Wash fastness and leveling properties may be altered by substitution. The shade can be varied from brilliant blue to green by appropriate amines. Araliphatic and cycloaliphatic amines lead to brilliant blue shades. A similar effect is exhibited by sterically hindered aromatic amines such as mesidine. These products are more light fast than the derivatives of bromamine acid. Among the unsymmetrically substituted dyes derived from 1-amino- (or 1-alkylamino-) 4-haloanthraquinones, the 1-alkylaminoanthraquinones have the lower light fastness. Exceptions are the derivatives of the 1-*sec*-alkylamino-4-haloanthraquinones. Introduction of alkoxy- (or aryloxy) groups into position 2 shifts the shade of the 4-arylamino-1-aminoanthraquinones to a bright violet.

244 C.I. Acid Green 25

245 C.I. Acid Green 41

246 Greenish Blue

247 Greenish Blue

248 C.I. Acid Violet 42

Examples are **244**, C.I. Acid Green 25, 61570 [*4403-90-1*] [5, p. 215] (e.g., Alizarine Cyanine Green G, Bayer); **245**, C.I. Acid Green 41, 62560

[*4430-16-4*] [3, p. 35]; **246** [406] and **247** [407] are greenish-blue dyes; **248**, C.I. Acid Violet 42, 62026 [*6408-73-7*] [3, p. 48] (e.g., Supracen Violet 3 R, Bayer).

1-Amino-4-hydroxyanthraquinones with External Sulfonic Acid Groups. By one-sided reaction of quinizarin with arylamines, followed by sulfonation, violet leveling dyes are obtained. Derivatives of 1-amino-4-hydroxy-2-phenoxyanthraquinones were developed specially for polyamide fibers.

Examples are **249,** C.I. Acid Violet 43, 60730 [*4430-18-6*] [3, p. 48] (e.g., Supracen Violet 3 B, Bayer); **250** bluish brilliant red dye [408].

249 C.I. Acid Violet 43

250 Bluish Brilliant Red

Anthrapyridones. Of the anthraquinone dyes with meso rings only species sulfonated in the arylamino or phenoxy groups derived from 6-arylamino-3-methyl-, 6-arylamino-1-carbethoxy-4-methyl-, and 6-arylamino-1-benzoyl-4-phenoxy-anthrapyridones are known to have been used commercially. They once were very important as light-fast, red, leveling dyes but have lost their position with the availability of the fast, red, azo dyes.

An example is **251,** C.I. Acid Red 82, 68205 [*2611-80-5*] [3, p. 40].

251 C.I. Acid Red 82

Other Acid Anthraquinone Dyes. In addition to the dyes in the preceding classes, a whole series of specially developed products is available. For instance, derivatives of the anthrimide or carbazole series are known to be very light-fast gray and brown wool dyes. The post-sulfonation products of 1,5- (and 1,8-) diarylaminoanthraquinones are violet dyes commonly applied as mixtures.

An example is **252,** C.I. Acid Black 48, 65005 [*1328-24-1*] [5, p. 216] (e.g., Alizarine Light Grey BBLW, BBL, Bayer).

252 C.I. Acid Black 48

3.2.2. Direct Dyes

Compared to direct azo dyes, the direct anthraquinone dyes have lower tinctorial strengths and are therefore far less economical to use. They have lost most of their importance. Only a few special green dyes have retained their importance. Direct green cotton dyes can be produced by coupling a blue bromamine acid dye and a yellow azo dye via ureido or diaminotriazine bridges.

An example is compound **253,** C.I. Direct Green 28, 14155 [*6471-09-6*].

253 C.I. Direct Green 28

3.2.3. Reactive Dyes

The shades of the commercial reactive anthraquinone dyes range generally only from violet to blue. These dyes are used specifically for the production of fast brilliant blue shades on cellulose fibers. Their synthesis begins with basic dyes linked to the reactive component via an amino group. These amino or alkylamino group may be positioned directly on the anthraquinone nucleus (rare) or on an aryl or cycloalkyl residue. Another possible linkage involves aminomethylarylaminoanthraquinones.

Nearly all reactive anthraquinone dyes are derivatives of bromamine acid (see Section 3.2.1). To obtain a sufficiently soluble dye, at least one additional sulfonic acid group must be present in the molecule. This may be positioned directly on the anthraquinone nucleus, in the 5 to 8 positions, or may be linked to the arylamino substituent. It is also possible to introduce one or two additional sulfonic acid groups together with a reactive group.

A large number of fiber-reactive components has been proposed for the preparation of reactive anthraquinone dyes (→ Reactive Dyes). Reactive carboxylic acid derivatives, such as 2,3-dichloroquinoxaline-6-carbonyl chloride and α-bromoacryloyl chloride, or reactive chloro or fluoro heterocyclics, such as derivatives of triazine or pyrimidine, have become important industrially.

Dyes with reactive vinylsulfonyl or β-sulfatoethylsulfonyl groups are constructed on a somewhat different principle.

The various options in printing or continuous dyeing are affected more by the choice of the reactive group than by the chromophoric system.

Examples of this class of dyes are **254,** C.I. Reactive Blue 2, 61211 [*12236-82-7*] (e.g., Procion Blue H-B); **255,** C.I. Reactive Blue 4, 61205 [*13324-20-4*] (e.g., Procion Blue MX-R); **256,** reddish brilliant blue [409]; **257,** brilliant blue [410]; **258,** blue [411]; **259,** brilliant blue [412]; **260,** C.I. Reactive Blue 19, 61200 [*2580-78-1*] (e.g., Remazol Brilliant Blue R, Hoechst); **261,** reddish brilliant blue for wool [413].

3.3. Cationic Dyes

Water-soluble cationic anthraquinone dyes have become valuable for dyeing polyacrylonitrile fibers. Dyes with external ammonium groups are especially important. Dyes with quaternary ammonium groups as well as salts of sufficiently basic amino derivatives are used also. The majority of commercial dyes are alkylamino- or arylaminoanthraquinones that carry an ammonium group on the alkyl group, such as trialkylammonium, cycloammonium, or hydrazonium residue. A protonated dialkylamino group also may be present. Most of these dyes are derived from 1,4-diaminoanthraquinone.

Examples are **262,** a blue dye [307], **263,** a reddish-blue dye [284], **264,** a greenish-blue dye [307], and compound **265,** a blue dye used for wet-spun fibers while they are still gels [280].

Abstract

Allergic reactions cause a number of acute and chronic diseases. The *antigen* or *allergen* causing the allergic reaction is usually a protein, a polysaccharide, or a low molecular mass compound (hapten) bound to an endogenous protein. Antigens induce the synthesis of antibodies, which are serum proteins, referred to as immunoglobulins (Igs). Antigen cross-linking of the IgE molecules leads to cellular responses involving release of preformed mediators, e.g., histamine. *Antihistamines* or histamine H_1 receptor antagonists are used in the treatment of allergic diseases. In contrast to the first-generation or classical antihistamines the second-generation antihistamines do not have the side effects sedation, fatigue, and drowsiness. Mast cells are the predominant storage site for histamine in most tissues. Cromolyn sodium or disodium cromoglycate (DSCG) probably

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

acts on certain types of chloride channels expressed in mast cells and sensory nerves.

Allergen immunotherapy is a well established and accepted treatment of allergic diseases. Immunogenic tolerance is achieved by applying gradually increasing quantities of an allergen vaccine to the sensitized patient. Allergen preparations derive from reference standards containing defined amounts of relevant allergens. For efficient and well-tolerated therapy extracts are physically or chemically modified or conjugated. Recombinant DNA technology offers a new standard of qualitiy by selecting the disease causing major allergens.

The development of an anti-IgE antibody (omalizumab, Xolair^{TM}) offers a unique and novel treatment not only for therapeutic but also for preventive applications in IgE-mediated diseases. Omalizumab is a DNA-derived monoclonal humanized antibody which is well tolerated by the immune system. Omalizumab binds in form of complexes to free IgE in the serum and interacts with any kind of IgE, but not with other immunoglobulines. Omalizumab leads to a downregulation of IgE receptors on mast cells and tissue cells in target organs. The substance showed immunomodulatory effects on dendritic cells and reduced significantly the number of eosinophils. Effects of treatment on allergic rhinitis and asthma have been evaluated in several studies.

1. Introduction

Allergic diseases are worldwide on the increase. Studies in several countries show that about 15 – 20 % of all adults suffer from one of the many different allergic disorders. Allergic reactions cause a number of acute and chronic diseases, such as conjunctivitis, rhinitis, dermatitis, gastroenteritis, asthma, and anaphylactic shock. Allergic responses are immediate reactions to specific foreign substances to which individuals have developed hypersensitivity. Sensitizing antigens come from a variety of environmental sources: they can be airborne (e.g., pollens, molds, animals dander and urine, house dust mites), taken up orally (e.g., foods, drugs) or be injected (insect bites, drugs). The *antigen* or *allergen* is usually a protein, a polysaccharide or a low molecular mass compound (hapten) bound to an endogenous protein to form an antigenic complex. Antigens induce the synthesis of antibodies. In sensitized individuals, the subsequent exposure to the antigen results in the initiation of a series of cellular reactions that lead to the symptoms observed in allergy. Antibodies are serum proteins, referred to as immunoglobulins (Ig) such as IgG, IgM, IgA, and IgE. Allergic responses have been divided into four general categories [6]. Type I, or *anaphylactic reactions* are mediated by IgE antibodies (reagin). The main targets of this type of reaction are the skin (urticaria, atopic dermatitis), the gastrointestinal tract (food allergies), the eyes (conjunctivitis), the respiratory tract (rhinitis, asthma) and the vascular system (anaphylactic shock). Type II *or cytolytic reactions* are mediated by IgG and IgM (mainly blood transfusion- and drug-induced hemolytic reactions). Type III or *Arthus phenomenon* is mediated by IgG (e.g., serum sickness); the type IV or *delayed-hypersensitivity reactions* are mediated by macrophages and T lymphocytes (e.g., contact dermatitis).

Allergy, in a strict sense, is an IgE-mediated inflammation. As a part of an allergic response to an antigen, reaginic antibodies (IgE) are generated and bound to the surface of mast cells and basophils via high affinity Fc receptors (FcεRI) that are specific for IgE [7]. Antigen cross-linking of the IgE-molecules leads to cellular responses involving release of preformed mediators (e.g., histamine), lipid mediator formation and release, and cytokin generation. Mast cells with their mediators can be regarded as central to the initiation and mediation of the early phase of allergic inflammation and may also be responsible for the initiation of chronic allergic inflammation. Recent investigations have shown that many other cells with their mediators, first of all, eosinophils and lymphocytes are also involved in the maintenance and progress of allergic inflammation. Histamine, lipid mediators, bradykinin, enzymes, and cytokins are among the many important chemical mediators characterized so far.

This article discusses drugs for the treatment of allergic disorders already available on the market or undergoing advanced clinical trials.

2. Antihistamines

Histamine [*51-45-6*], a potent effector agent in allergic diseases, was first synthesized in 1907 by WINDAUS and VOGT [8] without being aware of its pharmacological activities. DALE and LAIDLAW [9] suggested in 1910 that histamine might be responsible for anaphylaxis, and that its pharmacological activity resembled that of many tissue extracts. In 1927 BEST and coworkers [10] were able to show that histamine was present in fresh samples of liver and lung. This was followed by demonstration of its presence in a variety of other tissues, hence the name *histamine* after the Greek word for tissues, *histos*. Every mammalian tissue that contains histamine is capable of synthesizing it from histidine by action of L-histidine decarboxylase. Mast cells are the predominant storage site for histamine in most tissues, in the blood, histamine is stored in the basophil granulocytes. These cells synthesize histamine and store it in their secretory granules. Once released, histamine is metabolized via two major pathways: (1) methylation of the ring nitrogen in position 1, catalyzed by histamine-*N*-methyl-transferase; and (2) oxidative deamination by diamine oxidase.

Three types of histamine receptors exist: H_1, H_2, and H_3. Symptoms of allergy and anaphylaxis are mainly mediated via stimulation of histamine H_1 receptors. Other effects, notably gastric acid secretion and increase in cardiac rate, are the result of H_2 receptor activation. Some responses, such as the hypotension that results from vasodilatation, are mediated by both H_1 and H_2 receptors. H_3 receptors are presynaptic receptors on histaminergic nerve terminals. *Antihistamines* or histamine H_1 receptor antagonists are used in the treatment of allergic diseases. Antihistamines can be divided into two groups: the so-called classical or sedating and the modern, nonsedating antihistamines. All first-generation or classical antihistamines show the major side effects sedation, fatigue, and drowsiness to a varying extent. This can be put down to the fact that they interact with the H_1 receptors in the brain. Other side effects that apparently are caused by the antimuscarinic action of some of the first-generation antihistamines include dryness of the mouth, diplopia, and dysuria. All these effects are not observed with the modern, the second-generation H_1 receptor antagonists [11]. Following the introduction of the nonsedating antihistamines, sedating histamine H_1 receptor antagonists have been replaced almost completely by the new antihistamines. Members of the first generation of antihistamines have nowadays only a relatively limited therapeutic value. They are often given as multi-ingredient preparations for the treatment of cough and common cold. In some cases, an attempt has been made to find new indications for the first-generation antihistamines.

2.1. First Generation Antihistamines

Research on antihistamines was initiated in 1933 by FOURNEAU and BOVET [12], who observed that 2-(*N*-piperidinomethyl)-1,4-benzodioxane protected animals from histamine-induced bronchoconstriction.

The first recorded evidence of a histamine antagonist originates from BOVET and STAUB [13] from the Pasteur Institute who noticed that a compound designated F 929, (5-isopropyl-2-methyl-phenoxyethyl)-diethylamine, attenuated some of the actions of histamine.

This compound protected guinea pigs against lethal doses of histamine, and lessened the symptoms of anaphylactic shock. Isosteric replacement of the ether oxygen by an amino group led to F 1571.

This first ethylenediamine derivative was synthesized by FOURNEAU and its pharmacological actions were described by STAUB [14] in 1937,

who concluded that an ethylenediamine moiety is probably the basic structure of antihistamines. In fact, most H_1 antagonists have a tertiary amino group linked by a two or three atom chain to two aromatic substituents and conform to the general formula:

where Ar is aryl and X is nitrogen or a –C–O– ether linkage to the β-aminoethyl side chain [15, 16]. Sometimes the two aromatic rings are bridged, as in the tricyclic derivatives, or the ethylamine group may be part of a ring structure. Other variations also are possible [17].

2.1.1. Ethylenediamines

In 1942, phenbenzamine was introduced as the first clinically useful antihistamine [18].

Phenbenzamine

Synthesis of Ethylenediamines. Three different methods of synthesizing ethylenediamines are widely used [19]:

1) Reaction of tertiary chloroethylamines with secondary amines in the presence of a base, e.g., NaH, $NaNH_2$, $NaOC_2H_5$, or KOH.
2) Alkylation of secondary amines, such as *N*-(2-dimethylaminoethyl)aniline with benzyl chlorides in the presence of a strong base.
3) Reaction of reactive heterocyclic halogen compounds, such as 2-bromopyridine with secondary amines, such as *N*-(2-dimethylaminoethyl)-aniline, also in the presence of a strong base.

Antazoline [*91-75-8*], 4,5-dihydro-*N*-phenyl-*N*-(phenylmethyl)-1*H*-imidazole-2-methanamine, $C_{17}H_{19}N_3$, M_r 165.3. Hydrochloride [*2508-72-7*], *mp* 237 – 241 °C; sulfate [*24359-81-7*].

Antazoline is used for local application to the eye in allergic conjunctivitis.

Preparation: [20].

Trade name: Antistin (CibaVision); often combined with vasoconstrictor agents such as tetryzoline.

Chlorpyramine [*59-32-5*], *N*-[(4-chlorophenyl)methyl]-*N′*,*N′*-dimethyl-*N*-2-pyridinyl-1,2-ethanediamine, $C_{16}H_{20}ClN_3$, M_r 289.8. Hydrochloride [*6170-42-9*], *mp* 172 – 174 °C.

Preparation: [21].

Trade names: Synopen (Geigy), Chloropyribenzamine (Polfa); several multi-ingredient preparations.

Chlorothen [*148-65-2*], *N*-[(5-chloro-2-thienyl)methyl]-*N′*,*N′*-dimethyl-*N*-2-pyridinyl-1,2-ethanediamine, $C_{14}H_{18}ClN_3S$, M_r 295.8. Citrate [*148-64-1*], hydrochloride [*135-35-3*].

Chlorothen is synthesized by condensation of 5-chloro-2-thienylchloride and *N*,*N*-dimethyl-*N′*-(2-pyridinyl)ethylenediamine in the presence of sodium or potassium amide [22].

Trade name: Tagathen (Lederle).

Histapyrrodine [*493-80-1*], *N*-phenyl-*N*-(phenylmethyl)-1-pyrrolidineethanamine, $C_{19}H_{24}N_2$, M_r 280.4. Hydrochloride, *mp* 196 – 197 °C.

Preparation: [23].
Trade names: Domistan (Servier), Luvistin (Boehringer Ingelheim), Calcistin (Galenus).

Mepyramine [*91-84-9*], *N*-[(4-methoxyphenyl)methyl]-*N′*,*N′*-dimethyl-*N*-2-pyridinyl-1,2-ethanediamine, $C_{17}H_{23}N_3O$, M_r 285.4. Hydrochloride [*6036-95-9*], *mp* 143 °C; maleate [*59-33-6*].

Preparation: [24].
Trade names: Neo-Antergan (Rhône-Poulenc; Merck USA), Neo-Bridal (Bayer), Pyramal (Roxane). Several multi-ingredient preparations.

Methapyrilen [*91-80-5*], *N*,*N*-dimethyl-*N′*-2-pyridinyl-*N′*-(2-thienylmethyl)-1,2-ethanediamine, $C_{14}H_{19}N_3S$, M_r 261.4. Hydrochloride [*135-23-9*], *mp* 162 °C; fumarate [*33032-12-1*].

Methapyrilene is synthesized by heating a 2-thienyl halide with an alkali metal salt of *N*,*N*-dimethyl-*N′*-(2-pyridinyl)-1,2-ethanediamine [25].

Trade names: Thenylene (Abbott), Semikon (Beecham), Thionylan (Lilly).

Phenbenzamine [*961-71-7*], *N*,*N*-dimethyl-*N′*-phenyl-*N′*-(phenylmethyl)-1,2-ethanediamine, $C_{17}H_{22}N_2$, M_r 254.4. (Structural formula above.) Monohydrochloride [*2045-52-5*], *mp* 210 – 211 °C; dihydrochloride [*64335-73-5*]; citrate [*5956-46-7*].
Preparation: [26].
Trade names: Antergan (Rhône-Poulenc), Bridal (Bayer), Several multi-ingredient preparations.

Thenyldiamine [*91-79-2*] is the 3-thenyl isomer of methapyrilen. Hydrochloride [*958-93-0*]
Preparation: [27].
Trade names: Thenfadil (Sterling-Wintrop).

Thonzylamine [*91-85-0*], *N*-[(4-methoxyphenyl)methyl]-*N′*,*N′*-dimethyl-*N*-2-pyrimidinyl-1,2-ethanediamine, $C_{16}H_{22}N_4O$, M_r 287.3. Hydrochloride [*63-56-9*], *mp* 173 – 176 °C.

Thonzylamine is synthesized by treating the sodium salt of 2-(4-methoxybenzyl)aminopyrimidine with *N*,*N*-dimethyl-2-chloroethylamine [28].
Trade names: Tonamil (Ecobi).

Tripelenamine [*91-81-6*], *N*,*N*-dimethyl-*N′*-(phenylmethyl)-*N′*-2-pyridinyl-1,2-ethanediamine, $C_{16}H_{21}N_3$, M_r 255.3. Hydrochloride [*154-69-8*], *mp* 192 – 193 °C. Citrate [*6138-56-3*], *mp* 106 – 110 °C.

Preparation: [24, 29].
Trade names: Pyribenzamine (Ciba – Geigy), Azaron (Chefaro).

2.1.2. Ethanolamine Derivatives

Derivatives of aminoalkyl ethers were preferentially synthesized in the 1940s and 1950s in the United States. The most frequently used representative of this series is diphenhydramine that has been introduced into therapy in 1946.

In general, the histamine antagonistic potency of these basic ethers is lower than that of the ethylenediamines. Beside their antihistaminic activity, they have antimuscarinic and pronounced central sedative effects and are thus suited as sleeping aids. Because of their antiemetic properties they are used for prevention and treatment of motion sickness, emesis. Furthermore, these ethanolamine derivatives are commonly included in preparations used for the treatment of cold and cough.

Synthesis of Ethanolamines. In all known synthetic methods a benzhydryl unit is used as starting material [30]. Two synthetic routes are normally followed:

1) The sodium salt of a benzhydrol, prepared with NaH, $NaNH_2$, or $NaOC_2H_5$, is treated with an aminoethyl halide, e.g., dimethylaminoethyl chloride.
2) Sometimes a benzhydryl halide is condensed with an aminoethanol in the presence of potassium carbonate.

Bromdiphenhydramine [*118-23-0*], bromazine, 2-[(4-bromophenyl)phenylmethoxy]-*N*,*N*-dimethylethanamine, $C_{17}H_{20}BrNO$, M_r 334.3. Hydrochloride [*1808-12-4*], *mp* 144 – 145 °C.

Preparation: [31].

Trade names: Ambodryl (Parke – Davis), multi-ingredient preparations such as Ambenyl.

Carbinoxamine [*486-16-8*], 2-[(4-chlorophenyl)-2-pyridinylmethoxy]-*N*,*N*-dimethylethanamine, $C_{16}H_{19}ClN_2O$, M_r 290.8. Hydrochloride, *mp* 162 – 164 °C; maleate [*3505-38-2*].

Preparation: [32].

Trade names: Allergefon (Lafon), Clistin (McNeil), Ciberon (Taisho), Polistin T-Caps (Trommsdorff). Several multi-ingredient preparations.

Clemastine [*15686-51-8*], meclastine, 2-[2-[1(4-chlorophenyl)-1-phenylethoxy]ethyl]-1-methylpyrrolidine, $C_{21}H_{26}ClNO$, M_r 343.9. Hydrochloride, *mp* 152 – 155 °C; fumarate [*14976-57-9*].

Preparation: [33].

Trade names: Tavegil (Sandoz – Novartis), Telgin-G (Takeda). Some multi-ingredient preparations such as Dexa Tavegil.

Diphenhydramine [*58-73-1*], 2-(diphenylmethoxy)-*N*,*N*-dimethylethanamine, $C_{17}H_{21}NO$, M_r 255.3. Hydrochloride [*147-24-0*], *mp* 166 – 170 °C.

Preparation: [30]. To counteract the sedating effects, diphenhydramine is combined with 8-chlorotheophylline (Dimenhydrinate).

Trade names: Benadryl (Parke – Davis), Benadryl N (Warner – Lambert), Fenylhist (Mallard). Several multi-ingredient preparations.

Doxylamine [*469-21-6*], *N*,*N*-dimethyl-2-[1-phenyl-1-(2-pyridinyl)ethoxy]ethanamine, $C_{17}H_{22}N_2O$, M_r 270.4. Succinate [*562-10-7*], *mp* 100 – 104 °C.

Doxylamine is synthesized from phenyl-2-pyridinylmethyl carbinol and dimethylaminoethyl chloride in the presence of $NaNH_2$ in xylene [34]. It exhibits pronounced sedative effects. Therefore, doxylamine is mainly used as a sedative, a sleeping aid.

Trade names: Mereprine (Merrell), Hoggar N (Stada), Unisom (Pfizer).

Ebramine [*3565-72-8*], 2-[(4-bromophenyl)-1-phenylethoxy]-*N*,*N*-dimethylethanamine, $C_{18}H_{22}BrNO$. Hydrochloride [*13977-28-1*], *mp* 150 – 152 °C.

Preparation: [35].

Trade names: Bromadryl (Spofa).

Mephenhydramine [*3572-74-5*], 2-(1,1-diphenylethoxy)-*N*,*N*-dimethylethanamine, $C_{18}H_{23}NO$, M_r 269.4. Hydrochloride, *mp* 168 °C.

Compared with diphenhydramine the antihistaminic activity of mephenhydramin has been enhanced by the introduction of an additional methyl group.

Preparation: [36].

Trade names: Alphadryl (Spofa). Several multi-ingredient preparations.

Phenyltoloxamine [*92-12-6*], *N*,*N*-dimethyl-2-[2-(phenylmethyl)phenoxy]ethanamine, $C_{17}H_{21}NO$, M_r 255.4. Citrate [*1176-08-5*], *mp* 138 – 140 °C.

Preparation: [37].

Trade names: Phenyltoloxamine is available only in multi-ingredient preparations, e.g., Codipront (Mack Illertissen).

Trimethobenzamide [*138-56-7*], *N*-[[4-[2-(dimethylamino)ethoxy]phenyl]methyl]-3,4,5-trimethoxybenzamide, $C_{21}H_{28}N_2O_5$, M_r 388.5. Hydrochloride [*554-92-7*].

Preparation: [38].

Trade names: Anaus (Molteni), Tigan (Smith Kline Beecham).

2.1.3. Alkylamines

At the end of the 1940s, it was observed that appropriately substituted aminopropanes exhibit antihistaminic activities [39, 40]. Substituted aminopropanes have been introduced into therapy as antihistamines in the early 1950s. One of the remarkable features of these alkylamine derivatives is their strong and long-lasting antihistaminic activity. They are only moderately sedating and show some antimuscarinic properties. Among the stereoisomers, the dextrorotary form (D-form) is the eutomer (i.e., enantiomer with the higher bilological activity) [41].

Brompheniramine [*86-22-6*], 3-(4-bromophenyl)-3-(2-pyridinyl)-*N*,*N*-dimethylpropanamine, $C_{16}H_{19}BrN_2$, M_r 319.2. Maleate [*980-71-2*], *mp* 132 – 134 °C.

Preparation [42]:

where X = Br (bromopheniramine), Cl (chloropheniramine) or H (pheniramine).

Similarly to other pheniramine derivatives, brompheniramine can also be administered parenterally.

Trade names: Ilvin (Merck), Dimegan (Dexo). Several multi-ingredient preparations.

Chlorpheniramine [*132-22-9*], 3-(4-chlorophenyl)-3-(2-pyridinyl)-*N*,*N*-dimethylpropanamine, $C_{16}H_{19}ClN_2$, M_r 274.8. Maleate [*113-92-8*], *mp* 130 – 135 °C. Synthesis [42], formula see page 8. The racemate can be separated into the enantiomers; the D-form, dexchlorpheniramine, is active [43].

Trade names: Teldrin (SKF), D-form: Polaronil (Schering), Polaramin (Schering), Phenamin (Nycomed). Several multi-ingredient preparations, e.g., Codicaps (Thiemann).

Dimetindene [*5636-83-9*], *N*,*N*-dimethyl-3[1-(2-pyridinyl)ethyl]-1*H*-indene-2-ethanamine, $C_{20}H_{24}N_2$, M_r 292.4. Maleate [*3614-69-5*], *mp* 159 – 161 °C.

Preparation: Benzylmalonic acid is esterified with dihydropyran and reacted with sodium hydride and 2-dimethylaminoethyl chloride in toluene to give ditetrahydropyranyl-2-benzyl-2-(2-dimethylaminoethyl)malonate, which is cyclized with the help of polyphosphoric acid to 2-(2-dimethylaminoethyl)-indan-1-one. This compound reacts with 2-ethylpyridine and phenyllithium to give the carbinol, which is dehydrated by heating to dimetindene [44].

Trade names: Fenistil (Zyma), Forhistal (Ciba). Several multi-ingredient preparations.

Pheniramine [*86-21-5*], *N*,*N*-dimethyl-γ-phenyl-2-pyridinepropanamine, $C_{16}H_{20}N_2$, M_r 240.3. Maleate [*132-20-7*], *mp* 107 °C. (Formula and preparation see page 8).

Trade name: Avil (Hoechst). Several multi-ingredient preparations.

Tolpropamine [*5632-44-0*], 3-phenyl-3-(4-methylphenyl)-*N*,*N*-dimethylpropanamine, $C_{18}H_{23}N$, M_r 253.4. Hydrochloride [*3339-11-5*].

Preparation: [41].

Trade name: Pragman Gelee (Milanfarma).

Triprolidine [*486-12-4*], (*E*)-2-[1-(4-methylphenyl)-3-(1-pyrrolidinyl)-1-propenyl]pyridine, $C_{19}H_{22}N_2$, M_r 278.4. Hydrochloride [*550-70-9*], *mp* 116 – 118 °C; hydrochloride monohydrate [*6138-79-0*]. Synthesis [45]:

Triprolide

Trade names: Pro-Actidil (Wellcome), Venen (Tanabe). Several multi-ingredient preparations, e.g., Actifed (Warner – Lambert).

2.1.4. Piperazines

Buclizine [*82-95-1*], 1-[(4-chlorophenyl)-phenylmethyl]-4-[4-(1,1-dimethylethyl)phenyl]methyl]piperazine, $C_{28}H_{33}ClN_2$, M_r 433.0. Dihydrochloride [*29-74-8*].

Preparation: [46]. Buclizine is mainly used in the prevention of motion sickness and in combination with analgesics for treatment of migraine.

Trade names: Buclifen (Pfizer), Posdel (UCB). Several multi-ingredient preparations, e.g., Migralave N (Tremmler Pharma).

Chlorcyclizine [*82-93-9*], 1-[(4-chlorophenyl)phenylmethyl]-4-methylpiperazine, $C_{18}H_{21}ClN_2$, M_r 300.8. Hydrochloride [*1620-21-9*], *mp* 216 °C.

Preparation: [47].

Trade names: Di-Paralene (Abbott), Histantin (Wellcome).

Cinnarizine [*298-57-7*], 1-(diphenylmethyl)-4-(3-phenyl-2-propenyl)piperazine, $C_{26}H_{28}N_2$, M_r 368.5.

Preparation: Cinnarinzine is prepared by alkylation of 1-diphenylmethyl piperazine with 3-phenyl-2-propenyl chloride [48]. In addition to its antihistaminic activity, cinnarizine possesses Ca^{2+} channel blocking activity. Its vasodilator effect probably results from blocking the Ca^{2+} channels in the vascular smooth muscle cells. Therefore, cinnarizine is used in peripheral and central vascular diseases. Labyrinth disorders (e.g. vertigo, Ménière syndrome) are also often treated with cinnarizine.

Trade names: Stutgeron (Janssen), Aplactan (Eisai), Mitronal (Searle).

Clocinizine [*298-55-5*], 1-[(4-chlorophenyl)phenylmethyl]-4-(3-phenyl-2-propenyl)piperazine, $C_{26}H_{27}ClN_2$, M_r 403.0.

Preparation: [49].

Trade names: Clocinizine is used only in multi-ingredient preparations, e.g., Denoral (Rorer).

Cyclizine [*82-92-8*], 1-diphenylmethyl-4-methylpiperazine, $C_{18}H_{22}N_2$, M_r 266.4, *mp* 105 – 107 °C. Hydrochloride [*303-25-3*].

Preparation: Cyclizine is prepared by reaction of benzhydryl chloride and *N*-methyl piperazine [50]. It can be used not only in the treatment of allergic diseases, but also in the management of postoperative, irradiation or drug-induced vomiting. Cyclizine dependence has been suggested to occur when it is used in combination with analgesics in long-term therapy. For this reason, several countries have removed cyclicine from analgesic combination preparations.

Trade names: Marziné (Burroughs Wellcome). Some multi-ingredient preparations, e.g., Cyclimorph.

Flunarizine [*52468-60-7*], (*E*)-1-[bis(4-fluorophenyl)methyl]-4-(3-phenyl-2-propenyl)-piperazine, $C_{26}H_{26}F_2N_2$, M_r 404.5. Dihydrochloride [*30484-77-6*].

Flunarizine is the difluorinated derivative of cinnarizine. Thus, its preparation and therapeutic use are identical to those of cinnarizine.

Trade names: Sibelium (Janssen), Fluxarten (Beecham).

Hydroxyzine [*68-88-2*], 2-[2-[4-[4-(chlorophenyl)phenylmethyl]-1-piperazinyl]-ethoxy]ethanol, $C_{21}H_{27}ClN_2O_2$, M_r 410.0. Dihydrochloride [*2192-20-3*], *mp* 193 °C.

Preparation: [51]. Hydroxyzine has antihistaminic, antimuscarinic, and central nervous properties. Hydroxizine is used not only in the treatment of allergic diseases, but also as an anxyolitic.

Trade names: Atarax (Pfizer), Orgatrax (Organon).

Meclozine [*569-65-3*], mezlizine, 1-[(4-chlorophenyl)phenylmethyl]-4-[3-methylphenyl)methyl]piperazine, $C_{25}H_{27}ClN_2$, M_r 391.0. Dihydrochloride monohydrate [*31884-77-2*].

Preparation: The synthesis of meclozine is very similar to that of cyclizine.

Trade names: Postafen (UCB), Bonine (Pfizer), Veritab (Vista).

Niaprazine [*27367-90-4*], *N*-[3-[4-(4-fluorophenyl)-1-piperazinyl]-1-methylpropyl]-3-pyridinecarboxamide, $C_{20}H_{25}FN_4O$, M_r 356.4.

Preparation: [52].

Trade names: Nopron (Carrion).

Oxatomide [*60607-34-3*], 1-[3-[4-(diphenylmethyl)-1-piperazinyl]propyl]-1,3-dihydro-

2*H*-benzimidazol-2-one, $C_{27}H_{30}N_4O$, M_r 426.2.

Preparation: Oxatomide is synthesized by alkylation of 1-diphenylmethylpiperazine with 1-(3-chloropropyl)-1,3-dihydro-2*H*-benzimidazol-2-one in the presence of Na_2CO_3 [53]. In addition to its histamine H_1 receptor antagonistic effect, oxatomide may have mast-cell stabilizing activities [54].

Trade names: Tinset (Janssen), Celtect (Kyowa).

2.1.5. Piperidines

Bamipine [*4945-47-5*], 1-methyl-*N*-phenyl-*N*-(phenylmethyl)-4-piperidinamine, $C_{19}H_{24}N_2$, M_r 280.4. Dihydrochloride [*61732-85-2*].

Preparation: [55].

Trade names: Soventol (Knoll).

Diphenylpyraline [*147-20-6*], 4-(diphenylmethoxy)-1-methylpiperidine, $C_{19}H_{23}NO$, M_r 281.4. Hydrochloride [*132-18-3*].

Preparation: [160].

Trade names: Arbid N (Bayer), Lergobine (3M). Some multi-ingredient preparations.

Pipoxizine [*55837-21-3*], 2-[2-[2-[4-(Diphenylmethylene)piperidinyl]ethoxy]ethoxy]ethanol, $C_{24}H_{31}NO_3$, M_r 381.3. Hydrochloride, *mp* 144 – 145 °C. Synthesis [56]:

Pipoxizine

Trade names: Respacal (UCB).

Thenalidine [*86-12-4*], 1-methyl-*N*-phenyl-*N*-(2-thienylmethyl)-4-piperidinamine. $C_{17}H_{22}N_2S$, M_r 286.5. Tartrate, *mp* 170 – 172 °C.

Preparation: Thenalidine is synthesized by alkylation of 1-methyl-4-phenylaminopiperidine with 2-chloromethyl thiophene [57].

Trade names: Sandosten (Sandoz).

2.1.6. Phenothiazines

Alimemazone [*84-96-8*], 10-[3-(dimethylamino)-2-methylpropyl]phenothiazine, $C_{18}H_{22}N_2S$, M_r 298.5. Tartrate [*4330-99-8*].

Preparation: [58].
Trade names: Theralene (Rhône – Poulenc), Temaril (Allergan).

Dimethothiazine [*7456-24-8*], 10-[2-(dimethylamino)-propyl]-*N*,*N*-dimethyl-10*H*-phenothiazine-2-sulfonamide, $C_{19}H_{25}N_3O_2S_2$, M_r 391.6. Methanesulfonate [*7455-39-2*].

Preparation: [59].
Trade names: Banistyl (M & B), Migristene (Specia).

Dimelazine [*15302-12-2*], 10-[(1,3-dimethyl-3-pyrrolidinyl)methyl]-10*H*-phenothiazine, $C_{19}H_{22}N_2S$, M_r 310.1.

Trade names: Centrophene (Biosedra), Tacaryl (Westwood).

Dioxopromethazone [*13754-56-8*], 10-[2-(dimethylamino)propyl]-10*H*-phenothiazine-5,5-dioxide, $C_{17}H_{20}N_2O_2S$, M_r 316.2.

Trade names: Prothanon (LAW).

Hydroxyethylpromethazine [*7647-63-4*], (2-hydroxyethyl)dimethyl-(1-methyl-2-phenothiazi-10-ylethyl)ammonium chloride, $C_{19}H_{25}ClN_2OS$, M_r 364.9.

Preparation: [60].
Trade names: Aprobit (Kabi).

Isothipendyl [*482-15-5*], 10-(2-dimethylamino-2-methylethyl)-10*H*-pyrido[3,2-*b*][1,4]-benzothiazine, $C_{16}H_{19}N_3S$, M_r 285.4. Hydrochloride [*1225-60-1*] *mp* 222 – 223 °C. Preparation [61]:

Isothipendyl

Isothipendyl is more active than promethazine and less sedating [62].
Trade names: Theruhistin (Ayerst).

Mequitazine [*29216-28-2*], 10-(1-azabicyclo[2.2.2]oct-3-ylmethyl)-10*H*-phenothiazine, $C_{20}H_{22}N_2S$, M_r 322.5.

Preparation: [63]. Mequitazine has mild central sedating effects.

Trade names: Metaplexan (Rhône – Poulenc – Rorer), Butix (Fabre).

Methdilazine [*1982-37-2*], 10-[(1-methyl-3-pyrrolidinyl)methyl]-10*H*-phenothiazine, $C_{18}H_{20}N_2S$, M_r 296.4. Hydrochloride [*1229-35-2*], *mp* 187 – 189 °C.

Preparation: [64].

Trade names: Dilosyn (British Drug Houses), Tacaryl (Westwood).

Oxomemazine [*3689-50-7*], 10-(3-dimethylamino-2-methylpropyl)phenothiazine-5,5-dioxide, $C_{18}H_{22}N_2O_2S$, M_r 330.5. Hydrochloride [*4784-40-1*].

Preparation: [65].

Trade names: Doxergan (Rhône – Poulenc).

Promethazine [*60-87-7*], 10-(2-dimethylamino-propyl)phenothiazine, $C_{17}H_{20}N_2S$, M_r 284.4. Hydrochloride [*58-33-3*] *mp* 244 – 246 °C.

Preparation: [66]. Promethazine is synthesized from 10-phenothiazine-2-propyl chloride and dimethylamine in the presence of Cu. In addition to its antihistaminic activity, it has marked central sedative properties.

Trade names: Atosil (Bayer), Phenergan (Rhône – Poulenc, Wyeth), Hiberna (Yoshitomi). Several multi-ingredient preparations.

Propiomazine [*362-29-8*], 1-[2-(dimethylamino)propyl]-10*H*-phenothiazin-2-yl]-1-propanone, $C_{20}H_{24}N_2OS$, M_r 340.5. Hydrochloride [*1240-15-9*].

Preparation: [67].

Trade names: Propavan (Kabi), Indorm (Wyeth).

Thiazinamium [*2338-21-8*], trimethyl-(1-methyl-2-phenothiazin-10-ylethyl)ammonium methyl sulfate, $C_{19}H_{26}N_2O_4S_2$, M_r 410.6.

Preparation: Thiazinamium is prepared by reacting promethazine with dimethyl sulfate [68].

Trade names: Padisal (Bayer), Multergan (Specia).

2.1.7. Other Tricyclic Systems

Azatadine [*3964-81-6*], 6,11-dihydro-11-(1-methyl-4-piperidylidene)-5*H*-benzo[5,6]cyclohepta[1,2-*b*]pyridine, $C_{20}H_{22}N_2$, M_r 290.4, *mp* 124 – 126 °C. Dimaleate [*3978-86-7*]. Synthesis [69]:

Azatadine

Trade names: Idulian (Unilabo), Zadine (Schering).

Clobenzepam [*1159-93-9*], 7-chloro-10-(2-dimethylaminoethyl)-5,10-dihydro-11*H*-dibenzo[*b*,*e*][1,4]diazepin-11-one, $C_{17}H_{18}ClN_3O$, M_r 315.8, Hydrochloride [*2726-03-6*], *mp* 225 – 233 °C.

Preparation: [70].

Trade names: Tarpan (Wander).

Cyproheptadine [*129-03-3*], 4-(5*H*-dibenzo[*a*,*d*]cyclohepten-5-ylidene)-1-methylpiperidine, $C_{21}H_{21}N$, M_r 287.4. Hydrochloride [*969-33-5*], *mp* 252 – 254 °C. In addition to its antiallergic action cyproheptadine also exhibits an appetite-stimulating effect. For this reason, it is often used for promotion of weight gain.

Preparation [71]:

Cyproheptadiene

Trade names: Nuran (Frosst), Periactin (MSD), Peritol (EGYT). Some multi-ingredient preparations.

Ketotifen [*34580-13-7*], 4,9-dihydro-4-(1-methyl-4-piperidylidene)-10*H*-benzo[4,5]cyclohepta[1,2-*b*]thiophene-10(9*H*)-one, $C_{19}H_{19}NOS$, M_r 309.2. Hydrogen fumarate [*34580-14-8*], *mp* 192 °C.

Preparation: [71].
Trade names: Zaditen (Sandoz – Novartis). Some multi-ingredient preparations.

Mebhydroline [*524-81-2*], 2,3,4,5-tetrahydro-2-methyl-5-(phenylmethyl)-1*H*-pyrido[4,3-*p*]indole, $C_{19}H_{20}N_2$, M_r 276.4. 1,5-Naphthalendisulfonate [*6153-33-9*].

Preparation: [72].
Trade names: Omeril (Bayer).

Phenindamine [*82-88-2*], 2,3,4,9-tetrahydro-2-methyl-9-phenyl-1*H*-indeno[2,1-*c*]pyridine, $C_{19}H_{19}N$, M_r 261.4. Hydrogen tartrate [*569-59-5*], *mp* 165 – 167 °C.

Preparation: [73].
Trade names: Pernovin (Chinoin), Thephorin (Sinclair).

Pimethixene [*314-03-4*], 1-methyl-4-(9*H*-thioxanthen-9-ylidene)piperidine, $C_{19}H_{19}NS$, M_r 293.4, *mp* 120 – 121 °C. Synthesis [74]:

Pimethixene

Trade names: Muricalm (Sandoz – Novartis).

2.2. Second-Generation Antihistamines

Antihistamines of the second generation are generally free of sedation. However, this effect is dose-dependent. At higher doses and, consequently, at higher plasma levels of the drugs, mild sedative effects can be observed.

2.2.1. Ethanolamines

Setastine [*64294-95-7*], 1-[2[1-(4-chlorophenyl)-1-phenylethoxy]ethyl]hexahydro-1*H*-azepine, $C_{22}H_{28}ClNO$, M_r 357.9. Hydrochloride [*59767-13-4*].

Preparation: [75].
Trade names: Loderix (EGIS).

2.2.2. Alkylamines

Acrivastine [*87848-99-5*], (*E*,*E*)-3-[6-[1-(4-methylphenyl)-3-(1-pyrrolidinyl)-1-propenyl]--2-pyridinyl]propenoic acid, $C_{22}H_{24}N_2O_2$, M_r 348.4.

Preparation: [76].
Trade names: Semprex (Glaxo – Wellcome).

2.2.3. Piperazines

Cetirizine [*83881-51-0*], 2-[4-[1-(4-chlorophenyl)phenylmethyl]-1-piperazinyl]ethoxy]acetic acid, $C_{21}H_{25}ClN_2O_3$, M_r 388.5. Dihydrochloride [*83881-52-1*].

Preparation: [77]. Cetirizine is a metabolite of hydroxizine with a long plasma half-life.

Trade names: Zyrtec (UCB), Reactine (Pfizer).

2.2.4. Piperidines

Astemizole [*68844-77-9*], 1-(4-fluorophenyl)-methyl-*N*-[1-[2-(4-methoxyphenyl)ethyl]-4-piperidinyl]-1*H*-benzimidazol-2-amine, $C_{28}H_{31}FN_4O$, M_r 458.3, *mp* 149 °C. Synthesis [78]:

Astemizole

Astemizole is a strong histamine H1-receptor antagonist with an extremely long elimination half-life. Prolongation of QTc interval and cardiac arrhythmias can be associated with its use [79].

Trade names: Histmanol (Janssen), Cilergil (Cilag), Almizol (Nobel).

Betotastine Besilate [*190786-44-8*], (+)-(*S*)-4-[4-[1-(4-chlorophenyl)-1-(2-pyridyl)-methoxy]piperidin-1-yl]butanoic acid monobenzenesulfonate, $C_{21}H_{25}ClN_2O_3 \cdot C_6H_6O_3S$, M_r 547.1.

Preparation: [80]. Under development by Tanabe Seiyaku and Ube.

Ebastine [*90729-43-4*], 1-[4-(1,1-dimethylethyl)phenyl]-4-[4-(diphenylmethoxy)-1-piperidinyl]-1-butanone, $C_{32}H_{39}NO_2$, M_r 469.0.

Preparation: [81].
Trade names: Ebastel (Almirall).

Fexofenadine [*153439-40-8*], 2-methyl-2-[4-[1-hydroxy-4-[4-(1,1-diphenylhydroxymethyl)-1-piperidinyl]butyl]phenyl]propionic acid, $C_{32}H_{39}NO_4$, M_r 501.2.

Fexofenadine is a metabolite of terfenadine (see page 17) and is free of cardiovascular side effects [82].
Trade names: Allegra (Hoechst Marion Roussel).

Levocabastine [*79516-68-0*], 1-[4-cyano-4-(4-fluorophenyl)cyclohexyl]-3-methyl-4-phenyl-4-piperidinic acid, $C_{26}H_{26}FN_2O_2$, M_r 417.2. Hydrochloride [*79547-78-7*].

Trade names: Livocab (Janssen), Levocon (Johnson & Johnson).

Mizolastine [*108612-45-9*], 1-(4-fluorobenzyl)-2-[4-[*N*-(3,4-dihydro-4-oxopyrimidin-2-yl)-*N*-methylamino]piperidin-1-yl]benzimidazole, $C_{24}H_{25}FN_6O$, M_r 432.5.

Preparation: [83]. Mizolastine is a potent nonsedating H_1-receptor antagonist providing satisfactory symptom relief in allergic rhinitis and urticaria [84].
Trade names: Mizollen (Synthelabo).

Noberastine [*110588-56-2*], 3-[(5-methyl-2-furanyl)methyl]-*N*-4-piperidinyl-3*H*-imidazo[4,5-*b*]pyridin-2-amine, $C_{17}H_{21}N_5O$, M_r 311.1.

Under development by Cilag (phase III). During clinical trials noberastine did not produce any sedative effects.

Terfenadine [*50679-08-8*], 4-(1,1-dimethylethyl)-1-[1-hydroxy-4-[4-(1,1-diphenylhydroxymethyl)-1-piperidinyl]butyl]benzene, $C_{32}H_{41}NO_2$, M_r 471.2.

Due to its arrhythmogenic activity, terfenadine has been replaced by its metabolite, fexofenadine (see page 17) [85].

Trade name: Teldane (Hoechst Marion Roussel).

2.2.5. Phthalazinones

Azelastine [*58581-89-8*], 4-[(4-chlorophenyl)methyl]-2-(hexahydro-1-methyl-1*H*-azepin-4-yl)-1(2*H*)-phthalazinone, $C_{22}H_{24}ClN_3O$, M_r 381.7. Hydrochloride [*37932-96-0*], *mp* 225 – 229 °C. Synthesis [86]:

Azelastine

Azelastine has potent, long-lasting histamine H_1-receptor blocking activity and several other interesting anti-inflammatory properties related to its antiallergic efficacy [86].

Trade names: Allergodil, Rhinolast (ASTA Medica).

2.2.6. Others

Emedastine [*87233-61-2*], 1-(2-ethoxyethyl)--2-(hexahydro-4-methyl-1*H*-1,4-diazepin-1-yl]-1*H*-benzimidazole, $C_{17}H_{26}N_4O$, M_r 302.2.

Trade names: Daren (Kanebo), Remicut (Kowa).

Epinastine [*80012-43-7*], 9,13*b*-dihydro-1*H*-dibenzo[*c*,*f*]imidazo[1,5-*a*]azepin-3-amine, $C_{16}H_{15}N_3$, M_r 249.1.

Preparation: [87].

Trade name: Alesion (Boehringer Ingelheim).

Loratadine [*79794-75-5*], 8-chloro-6,11-dihydro-11-(1-ethoxycarboxy-4-piperidinylidene)-5*H*-benzo[5,6]cyclohepta[1,2-*b*]-pyridine, $C_{22}H_{23}ClN_2O_2$, M_r 382.5.

Loratadine is a selective antihistamine for the relief of symptoms of allergic rhinoconjunctivitis and chronic urticaria [88]. In 1997, loratadine has been shown to produced cardiac arrhythmias probably via blocking cardiac K^+ channels [89]. However, the concentrations at which this blockade occurred were much higher that the observed therapeutic plasma levels [90].

Trade name: Claritin (Schering – Plough), Lisino (Essex Pharma).

2.2.7. Combinations of Antihistamines and Sympathomimetic Agents

Antihistamines are often combined with sympathomimetic agents. For oral administration, indirectly acting sympathomimetics (e.g., pseudoephedrine) are preferred. Combinations for topical applications contain α-adrenergic agonists

(e.g., oxymetazoline). Recently it has been demonstrated that pseudoephedrine might increase the stroke risk. As regards combinations for topical applications, it should be kept in mind that long-term application of α-adrenergic compounds may cause serious undesired effects (rebound effect, nasal congestion).

2.3. Inhibitors of Histamine Synthesis

Tritoqualine [*14504-73-5*], 7-amino-4,5,6-triethoxy-3-(5,6,7,8-tetrahydro-4-methoxy-6-methyl-1,3-dioxolo[4,5-*g*]-isoquinolin-5-yl)--1(3*H*)isobenzofuranone, $C_{26}H_{32}N_2O_8$, M_r 500.5.

Preparation: [91].
Trade names: Inhibostamin (Zyma), Livalfa (Mitsubishi).

3. Mast Cell Stabilizing Agents

The prototype drug, disodium cromoglycate resulted from research on khellin, a chromone 2-carboxylic acid derived from the Middle Eastern herb *Ammi visnaga* [92]. Cromolyn sodium or disodium cromoglycate (DSCG) was synthesized in 1965 and introduced as a prophylactic, nonbronchodilating anti-inflammatory drug into the therapy of allergic disorders. Although DSCG was initially thought to be merely a mast cell stabilizer, subsequent pharmacological studies showed that it has multiple effects. Probably, it acts on certain types of chloride channels expressed in mast cells and sensory nerves [93]. Penner et al. [94] described the existence of a small conductance chloride channel in rat peritoneal mast cells. Activation of this channel causes an influx of chloride ions and results in hyperpolarization of the membrane which then drives a calcium influx, leading to degranulation. Disodium cromoglycate blocks these intermediate conductance channels which are activated after immunological stimulation [95]. Since cromones are practically not absorbed in the gastrointestinal tract, they must be administered by inhalation. All attempts to develop orally active cromones have been unsuccessful until now.

Amlexanox [*68302-57-8*], 2-amino-7-(1-methylethyl)-5-oxo-5*H*-[1]benzopyrano[2,3-*b*]pyridine-3-carboxylic acid, $C_{16}H_{14}N_2O_4$, M_r 298.2.

Amlexanox acts in two ways. Besides its membrane-stabilizing property amlexanox also inhibits leucotriene-mediated effects [101].
Preparation: [100].
Trade name: Solfa (Takeda).

Disodium cromoglycate [*15826-37-6*], DSCG, cromolyn sodium, 5,5′-[(2-hydroxy-1,3-propanediyl)bis(oxy)]bis[4-oxo-4*H*-1-benzopyran-2-carboxylic acid]disodium salt, $C_{23}H_{14}Na_2O_{11}$, M_r 512.3.

Preparation: [96].
Trade names: Intal, Adrane (Fisons).

Lodoxamide [*53882-12-5*], 2,2′-[(2-chloro-5-cyano-1,3-phenylene)diimino]bis[2-oxoacetic acid], $C_{11}H_6ClN_3O_6$, M_r 311.6.

Trometamol (2-amino-2-(hydroxymethyl)-1,3-propanediol) salt [*63610-09-3*]. Lodoxamide is an antiallergic drug acting as a mast-cell stabi-

lizer, which is effective in the treatment of allergic conjunctivitis [99].

Trade names: Alomide (Alcon), Lomide (Pharmacia & Upjohn).

Nedocromil [*69049-73-6*], 9-ethyl-6,9-dihydro-4,6-dioxo-10-propyl-4*H*-pyrano[3,2-*g*]quinoline-2,8-dicarboxylic acid, $C_{19}H_{17}NO_7$, M_r 371.1. Disodium salt [*69049-74-7*].

Nedocromil sodium acts mainly by inhibiting the release of inflammatory mediators. It has a stabilizing action on mast cells similar to that of DSCG. Nedocromil is capable of inhibiting chloride ion flux in mast cells, epithelial cells, and neurons. This feature may explain why it can prevent responses such as mast cell degranulation and neuronal activation [97]. Nedocromil is given by inhalation in the prophylactic control of asthma and rhinitis [98].

Trade name: Tilade (Rhône – Poulenc – Rorer).

4. Allergen Preparations for Desensitization

The aim of allergen immunotherapy (hyposensitization, desensitization) is to achieve allergen tolerance in the atopic patient by administering gradually increasing quantities of an allergen vaccine. This treatment was first used by Noon [102] and Freeman [103] in 1911 for allergic rhinitis on an empirical basis. Since then, immunotherapy has become a widely accepted method of treatment in IgE-mediated allergic diseases, caused by various seasonal or perennial inhalant allergens.

Since the 1970s venom immunotherapy is the standard of care for hymenoptera sting-induced systemic allergic reactions [104]. Venom immuntherapy results in significantly lower risk of systemic reactions even 10 to 20 years after therapy is stopped [105, 106]. Knowledge has been gained about the mechanism of action of immunotherapy. Like vaccines allergen extracts act as immune modifiers, so it seems justified to call them allergen vaccines. The important role of T_H1 and T_H2 lymphocytes has been explored as well as the cytokine regulation of the immune response [107]. Immunotherapy is the only treatment that may affect the natural course of allergic diseases, especially the chronification of inflammation of the respiratory tract [108 – 111]. Successful immunotherapy is dependent on the quality of allergen vaccines. The vaccines have to be standardized and manufactured properly with batch-to-batch consistency.

The ideal allergen vaccines permit a maximum efficacy while minimizing the incidence of adverse reactions. The pharmaceutical industry is constantly developing and investigating safer and at the same time equally or more effective forms of therapies. The molecular allergen characterization by recombinant DNA technology leads to novel forms of diagnostics and immunotherapy based on recombinant allergens [112 – 114]. Recombinant allergens identify exactly those IgE-binding molecules responsible for the allergic reaction.

4.1. Properties of Allergens

Allergenic components are most often of a proteinaceous nature. Their molecular weight ranges between 5 and 70 kD. Pollens of grasses, trees, and weeds are the main source of disease-causing allergens, followed by dust mites, molds, pets, and food. The allergic reaction to insect stings represents a special form, because it will not elicit any chronic inflammatory organic disease, but usually lead to a local or even systemic life-threatening anaphylactic shock. Some molecules bind as haptens to human proteins and lead only as a protein complex to allergic reactions.

Those allergenic parts to which most patients respond with formation of antibodies are called major allergens, those less often answered by an immunologic response minor allergens. A special and important kind of allergens are the so-called profilines. They are highly cross-reactive proteins with a similar amino acid structure found in related or nonbotanical related plants, food, or even in human cells. Patients who are sensitized to profilines are allergic to a broad

Table 1. Physicochemical properties of a choice of purified allergens (Comprehensive list under [117])

Species	Common name	Allergen	Comment	Aa_length

spectrum of allergens. The fragments of allergens which bind to the T helper cells or B cells are called epitopes. Molecules of major antigens may possess 2–5 major epitopes, the total number of epitopes per allergen molecule may be much higher. Each epitope includes 8–15 amino acid residues. The allergen molecules have no physical or chemical features which distinguish them from any other proteinic antigens except that they are relatively small, and in some individuals give rise to initiation and maintenance of IgE production. Several hundred major allergen

molecules have been isolated and characterized up to now, and they have been shown to possess different biological properties, such as enzymes or to be involved in transport, reproduction or secretion [115, 116]. A comprehensive list of allergens whose amino acid sequences are known at present can be found in [117]. The nomenclature follows the recommendation of the WHO. The name of an allergen is formed out of the first three letters of the latin word, followed by the first letter of the accompanying adjective and then numbered. Some of the most common allergens are listed in Table 1.

4.2. Raw Materials

Raw materials for allergen immunotherapy are the biologic materials containing the allergenic components. The allergen raw material should be selected from relevant sources. Instructions for harvesting, storage, extraction, and purification have been described by the International Union of Immunologic Societies (IUIS) [118], in the Nordic Guidelines [119] and by the European Union [120] in order to achieve good batch-to-batch consistency of allergenic potency. Manufacturing of allergen extracts should be based on The Code of Good Manufacturing Practice (GMP) [121]. Figure 1 shows the production process of allergenic products.

4.3. Allergen Standardization

A prerequisite for standardization of allergen preparations extracted from well-defined source materials is that the content of major and minor allergens and the relation between these allergens is constant from batch to batch [122]. The most common vaccines used in clinical allergy practice are now available as standardized products. However, for some vaccines standardization is neither feasible nor economically possible. Several reference standards of widespread allergens containing defined amounts of relevant allergens are maintained under stable conditions [104]. These standards have been produced as part of the WHO/IUIS allergen standardization program for a number of vaccines [123]. Based on the precision of methods used for estimation of relative potency, the FDA and the Nordic Council on Medicine require a maximum variation in activity between batches of the same allergen from 50 to 200 % of the labeled value [104].

Methods of Standardization. The former classification in protein nitrogen units or weight/volume estimates is no longer used. Standardized products have been tested for potency both in vivo and in vitro using methods for detection of IgE antibodies to allergens. Using the technique of skin testing, allergen vaccines can be defined in biological units. The size of the allergen induced wheal is compared to a histamine reference solution (1 mg/mL). The allergen solution which produces a medium wheal in sensitized persons receives one HEP/mL (histamine equivalence prick) [119]. For representative results, however, this method depends on the availability of allergic and, moreover, comparable patients. The inhibition of the binding capacity of IgE antibodies is determined with methods derived from radioallergosorbent test (RAST)-inhibition. Those tests for measurement of allergenic potency are required by the European Pharmacopoeia [115]. International reference extracts are withheld by the WHO. Manufacturers rely on definite values for quality controls. One international reference value is defined as 100 000 international units (IU). Standardized extracts show improved consistency to nonstandardized ones. This holds true both for extracts produced by different manufacturers and different batches produced by the same manufacturer [124]. The biologic effects of standardized extracts have been tested and thus the range of major allergen levels is much narrower than in nonstandardized products. However, some variation occurs with in vivo and in vitro tests, and it may be difficult to compare total allergenic potency of vaccines produced by different manufacturers. The composition of the vaccine can be determined by methods such as enzyme-linked immunosorbent assay (ELISA) techniques, sodium dodecyl sulfate – polyacrylamide gel (SDS – PAGE) electrophoresis, isoelectric focusing, IgE immunoblotting and crossed immunoelectrophoresis/crossed radioimmunoelectrophoresis (CIE/CRIE) [125].

Current Analysis Techniques. DNA and protein analysis offers excellent opportunities for standardization. The selection of the relevant

Figure 1. Production process of allergenic products according to [122]
CIE = crossed immunoelectrophoresis; CRIE = crossed radioimmunoelectrophoresis; RAST = radioallergosorbent test

disease-causing major allergens is best achieved by recombinant DNA technology [126]. The most important allergens such as pollens, mites, animal dander and insects have been cloned, sequenced and expressed. They show comparable IgE antibody binding to their natural counterparts and excellent reactivity in skin and in in vitro testing [127, 128]. With DNA and protein analysis allergen vaccines are characterized in terms of content of major allergen (nanograms or micrograms), and the consistency of each lot can be accurately monitored. Other techniques include high-performance liquid chromatography, capillary electrophoresis, and mass spectrometry [124].

Units. A critical problem in determining total allergenic potency, whether based on biologic or on in vitro assays, is the use of varying units over the years. Only two systems have been supported by authorities, i.e., the Nordic Biological Unit (BU/mL, former HEP) and the U.S. Bioequivalent Allergy Unit (BAU/mL). Both measuring methods are based on the skin sensitivity of sample patients clinically sensitive to the allergens in question. The unit BU/mL is similar and reproducible in different regions of Europe. 1 BU of common inhalant allergen has been shown to be equal to 1 ng ($\pm$ a factor of 2) of the most important major allergens [129]. In practice manufacturers use different terms for concentrations: TE

(therapeutical unit–concentration in three steps from 50 to 5000 TE/mL) is common besides SQ-E (standardized qualitiy units–concentration in four steps from 100 to 100 000 SQ-E/mL), AUeq (allergy units equivalent–concentration 20 000 AUeq/mL), and SU (standardized units–concentration in three steps from 300 to 2000 SU/mL). All extracts with common allergens are standardized according the content of the major allergen. Yet there are no obligatory prescriptions for the total major allergen dose. Concentrations differ between manufacturers and therefore a switch among products should be avoided.

4.4. Allergen Vaccines for Immunotherapy

Allergen vaccines are manufactured in different preparations. Formerly, aqueous allergen vaccines were most commonly employed for antiallergic immunotherapy, mainly for venom and inhalant allergies. Depot and modified vaccines have been developed in an attempt to make immunotherapy more effective and reduce side effects. The principle of preparing modified vaccines is to reduce or remove allergenicity, e.g., the capacity to induce IgE-mediated reaction. At the same time the immunogenicity, which is the capacity to modulate the immune system and maintain clinical efficacy should be preserved or increased.

Modification. For safer and more efficient therapy, extracts are prepared as depot vaccines in different varieties. *Physical modification* means the adsorption of allergens on aluminum, calcium phosphate, or tyrosine, or trapping of allergens in liposomes. Allergenic reactivity concerning adverse reactions can be reduced by *chemical modification* of allergens to the so-called allergoids, such as formaldehyde-, glutaraldehyde- and alginate-modified vaccines. Combinations of physically and chemically modified vaccines include tyrosine-adsorbed glutaraldehyde-modified vaccines and aluminum hydroxide adsorbed- formaldehyde-modified vaccines. A new technique is the *conjugation of allergen* to immunostimulatory bacterial molecules. Monophosphoryl-Lipid A (MPL®) has been introduced as such a novel adjuvant since 2001. The preparation derived from the lipopolysaccharide of *Salmonella Minnesota* R595 and has Th1-inducing effects [130, 131]. This effect is long-lasting and thus the number of vaccine injections can be significantly reduced.

Allergen mixtures present several problems. Excessive dilution by multiple allergens may result in suboptimal doses of individual allergens. Further, the potency of individual allergens may deteriorate more rapidly when diluted or mixed with other allergen vaccines. Some allergens possess enzymatic activity which can alter the composition of other allergens [104]. Allergen vaccines should be distributed as either vaccines from a single source material or mixtures of related cross-reacting allergen vaccines. For any mixture of allergen vaccine stability data and data on clinical efficacy should be available [104].

4.5. Storage

Allergen vaccines are protein solutions that are labile at elevated temperatures. Therefore, sterilization can only be achieved by filtration. Solutions may be destroyed by microbial and enzymatic degradation, so they routinely contain preservatives and should be stored in a refrigerator between 2 and 8 °C. The most common preservative is phenol in concentrations of 0.2–0.5 %.

Concentrated aqueous extracts in 50 % glycerin that are only to be used for skin prick testing remain stable for about three years if stored at 4 °C. Diluted extracts lose their potency more rapidly [132]. To avoid loss of potency by adsorption of active components on the surfaces of containers and syringes, Tween 20 (an ethoxylated sorbitan ester) and human serum albumin have been employed. Vials should be labeled in accordance with the requirements of regulatory authorities. Labeling includes a designation of relevant units (see Units) obtained by an approved method.

4.6. Uses

Allergenic extracts are used for diagnosis and as vaccines for treatment.

4.6.1. Diagnostic Use

Skin testing with concentrated solutions of allergens is used to detect the individual sensitivities of an allergic patient. The most common techniques are the prick test and the intracutaneous test. The *prick test* is performed by puncturing the skin with a sterile lancet through a small drop of the allergenic extract. *The intracutaneous (i.c.) test* consists of injecting a minute amount (ca. 0.02 mL) of an allergen extract into the superficial layers of the skin. This method is more sensitive than the prick test, and the concentration of the test solution must be 10 – 100 fold lower than that for prick testing. In cases of sensitivity both tests will result in the development of a wheal and erythema reaction within 15–20 min. To confirm clinical relevance of an allergen in selected cases the nasal and/or bronchial provocation test is performed. A small amount of adequately diluted allergenic extract is instilled into the nose or inhaled as nebulized aerosol. A positive reaction is indicated by typical allergic symptoms and can be quantified by special measurement procedures.

4.6.2. Therapeutic Use—Immunotherapy

Immunotherapy has been accepted as an efficient treatment for allergic rhinitis and hay fever since the early 20th century. Besides allergen avoidance immunotherapy is the only chance that may modify the natural course of the disease, e.g., the development from rhinitis to asthma. Nevertheless, different points of view exist concerning immunotherapy and asthma. According to the consensus report on diagnosis and management of asthma of the National Institutes of Health immunotherapy for asthma is only rarely used in the United Kingdom or even not recommended following the British Thoracic Society guidelines [133, 134]. Immunotherapy treatment of allergic diseases including asthma is widely accepted in the USA and in European countries except Scandinavia.

Immunotherapy is absolutely indicated for patients who had severe IgE-mediated anaphylactic reactions to bee and wasp stings [135]. Hymenoptera venom is the only allergen for which an efficacious maintenance dose has been securely established (e.g., 100 μg of purified venom, corresponding to about two bee stings or five to ten wasp stings) [136]. Immunization with venoms regularly results in essentially complete protection [105, 106, 137].

Mechanism of Immunotherapy. In former years the efficacy of immunotherapy was measured by decrease of IgE or increase in IgG antibodies. In the mid-1990s it has been suggested that immunomodulation plays a major role in immunotherapy. Immunotherapy alters the balance of cytokines released from T helper lymphocytes in the respiratory tract, with a shift from the T_H2 cells—that release interleukin-4 (IL-4) and interleukin-5 (IL-5) in association with allergic inflammation—to T_H1 cells that release γ-interferon, which inhibit T_H2 cells [136, 138]. Successful immunotherapy might then be associated with a shift in IL-4/γ-interferon production either as a consequence of down regulation T_H2 cells responses or increased T_H1 cells responses. IL-10 has been found to play an important role. Subsequent to immunotherapy allergen-specific IL-10 will increase even in the respiratory mucosa. IL-10 mediates the immunotolerogenic effects by inducing the B cells to produce IgG4, by inhibition of IgE-dependent mast-cell activation and inhibition of eosinophil cytokine production and suppression of IL-5 [139]. Different mechanisms may be valid in venom immunotherapy in nonatopic persons and in immunotherapy with inhalant allergens in atopic patients. Until now no measurable parameters of patient characteristics or symptom severity have been found that can predict or correlate with a successful outcome [132].

Administration. Immunotherapy is started with very small amounts of allergen vaccine injected into the arm every two weeks. The allergen concentration is slowly increased until the maximum tolerated dose is reached. The intervals of injection may then be prolonged to about four weeks. A maintenance dose of approximately 5 to 20 μg of major allergen (ragweed, grass, mite, cat) is associated with significant improvement in patient symptom scores [124]. In venom immunotherapy the usually recommended maintenance dose is 100 μg of venom protein. In pollen immunotherapy a reduced dose should be given during season to avoid serious reactions. Local reactions occur very often at the injection site, early reactions

within 20–30 min, some later than 30 min. Systemic reactions with generalized symptoms are the worse the earlier they occur. To minimize the risk of immunotherapy each patient should stay under supervision for at least 30 min after injection and every immunotherapy-practicing doctor has to be trained in the treatment of allergic shock and resuscitation [140].

New ways of immunotherapy, for instance oral, sublingual or local application of allergen vaccine have been tested . The sublingual way seems to be the most promising for allergic rhinitis and asthma. Efficacy and safety have been proven for children and adults in many trials. Compared to the subcutaneous route a much higher amount of allergen is necessary [139, 141]. A disadvantage might be that there is less control by the treating physician because patients take the needed dose at home. Moreover there are no experiences about long-time efficacy comparable to the decades of subcutaneous application.

Contraindications for immunotherapy include malignant and in immunodeficiency diseases, treatment with β-blockers, poor compliance, severe asthma, and significant cardiovascular diseases. During pregnancy treatment should not be started but may be continued.

4.6.3. Legal Aspects, Quality Requirements, and Safety

Only standardized extracts should be used for diagnosis and treatment. Potency should be quoted in allergy units or in micrograms of a major constituent whenever possible [137]. In the USA the registration of allergenic products is controlled by the FDA Center for Biologics Evaluation and Review (CBER), where a new Division of Allergenic Products and Parasitology (DAPP) deals with development, controlling, use, and safety of allergenic products [142]. Since 1998 in the EU allergenic extracts are registered by the Paul-Ehrlich-Institut (PEI–Bundesamt für Sera und Impfstoffe) which is also a WHO-Collaboration Center. The PEI is responsible for the examination and registration of allergenic extracts for diagnosis and therapy. Allergen products should be manufactured under conditions which comply with GMP.

Guidelines for immunotherapy with inhalant allergens and venoms have been published in the past ten years by the WHO, the European Academy of Allergy and Clinical Immunology (EAACI), the International Consensus Report on Asthma, the Global Strategy for Asthma Management and Prevention, the International Consensus Report on Rhinitis, the British Society for Allergy and Clinical Immunology (BSACI), the American Academy of Allergy, Asthma and Immunology (AAAAI), the American College of Allergy, Asthma and Immunology (ACAAI) , the International Union of Immunological Societies (IUIS) and the Deutsche Gesellschaft für Allergologie und Immunologie (DGAI) [104, 121, 124, 134, 135, 140, 143]. In immunotherapy the incidence of severe reactions is low. The mortality rate during immunotherapy is about one death per 2×10^6 injections [136]. A study carried out in the Mayo Clinic over a ten year period with 79 953 injections showed 0.137 % systemic reactions in an average time of 35 min after injection. The systemic reactions were equally frequent during the rising and maintenance phases [144]. Bernstein et al. reported in 2004 similar rates of fatal reactions to diagnostic or therapeutic procedures as published in previous surveys [145]. The PEI analyzed severe reactions to diagnostic and therapeutic allergen extracts in Germany in the time period from 1991 to 2000. The authors conclude that the benefits of allergy diagnosis and immunotherapy outweigh the risk of adverse reactions [146]. Diagnosis and therapy of allergic diseases should only be practiced by specially trained physicians. Extreme caution is necessary in treating any asthmatic individual [121, 143].

5. Anti-IgE-Omalizumab

The knowledge about mechanisms of the allergic reaction has opened new strategies for treatment of allergic diseases. A novel therapeutic principle in treating IgE-mediated allergic diseases forms the introducing of anti-IgE antibodies. The substance (former name rhuMAb-E25, new nomenclature omalizumab) is a recombinant humanized monoclonal antibody (see → Monoclonal Antibodies). The trade name is Xolair (Novartis).

5.1. IgE and its Role for the Allergic Response

The IgE was first identified in the 1960s. In the normal individual there are usually low levels of circulating IgE. The IgE is part of the physiologic mucosal defence in parasitic infections. In allergic patients TH-2 lymphocytes release cytokines under the influence of allergens which induce B cells to produce allergen-specific IgE. The priming of B cells is located mainly in the lymphatic tissue of the gastrointestinal and respiratory tract. The IgE molecule (Fig. 2) is built out of two identical heavy (H) and two light (L) chains, which are separated in variable (V) and constant (C) parts. All four chains form a Y-like molecule, whose upper part consists of two double and variable H and L chains. This part binds the specific antigen and is called Fab_2 (fragment antigen binding).The opposite site – called Fc (fragment crystallisable)–is formed out of two H chains and attaches to the cell-bound receptors. There are high- (FcεRI) and low-affinity (FcεRII) receptors on mast cells, basophils, other blood cells, and tissue cells in target organs. High-affinity receptors allow a sensitization of the individual even with low amounts of allergen. This effect lasts more longer than the normal two to three days half-life of the free circulating IgE. The FcεR receptor consists of an IgE-binding a chain, one β chain and two γ chains (Fig. 3). In an allergic individual the first contact with an allergen leads to a specific sensitization and an IgE formation. In further contacts with the disease-causing allergen the allergen proteins bind to the receptor–IgE complex in form of a cross-linking. By this reaction basophils degranulate immediately and release preformed substances such as histamine and TNF-α. On mast cells and tissue cells the bridging reaction starts to synthesize other substances such as leukotrienes, cytokines and prostaglandins, which are the main mediators of the late allergic response [4, 5].

Figure 3. The IgE receptor on basophiles. Modified according to [5].

5.2. IgE-Mediated Allergic Diseases

In sensitized individuals allergens cause intermittent or chronic diseases of the skin, eyes, airways, gastrointestinal tract and sometimes other organs. Allergic rhinitis and asthma are the most common allergen-induced diseases, mainly due to inhalant and less often to food allergens. It is estimated that 2–15 % of the European population suffer from asthma, in some countries allergy may affect over 50 % of children [147]. The release of IgE and other mediators of the allergic reaction cause a constant and chronic inflammation, which in the case of asthma will lead to often hospitalization, destruction of lung parenchyma and loss of quality of life. In Great Britain every second patient suffers from severe asthma symptoms. More than two millions of patients have a bad controlled asthma despite of comprehensive therapy [148]. Another important entity of allergic diseases are the anaphylactic IgE-mediated disorders. The individ-

Figure 4. Molecular structure of monoclonal antibody. Genes encoding the Ig L and H chains are shown on top and on the right side, respectively. With courtesy of B. Gysin, Novartis.

ual has been sensitized by an insect sting without having any following chronic disease. But the next venom sting may lead to an immediate life threatening anaphylactic reaction. A similar reaction may occur in patients who have been sensitized to some kind of drugs for instance penicillin.

5.3. Properties of Omalizumab

In the year 1992 a recombinant monoclonal anti-IgE antibody was cloned for the first time. A decade passed till the substance was ready for the commercial use in human beings. Omalizumab is a recombinant DNA-derived humanized monoclonal antibody (see → Monoclonal Antibodies) that selectively binds to human IgE. Omalizumab does not bind to other immunoglobulins such as IgG or IgA.

5.3.1. Chemistry and Production of Omalizumab

The first step in the generation of anti-IgE antibodies has been immunizing mouse with human IgE. The DNA of selected murine anti-IgE producing B cells and the DNA of human immunoglobulin IgG producing B cells are matched together and form a recombinant DNA. The selected hybridoma cell line produces the specific monoclonal antibody which subsequently was cloned into an industrial producer cell line. This cell line produces an anti-IgE antibody which is only 5 % of murine and 95 % of human origine (Fig. 4). The humanizing of the anti-IgE antibody achieves tolerance of the human immune system. The manufacturing process takes place in large bioreactors (Fig. 5). The final stage of the cultivation procedure needs fourteen days (Fig. 6). Purification is performed by several downstream processing steps (Tab. 2). Important factors of the produced antibody solution such as identity, content, purity, stability, biological activity and sterility are checked with

Sterility	MLT etc

different analytical methods (Tab. 3). Changes of the molecular heterogeneity that may occur over time are analyzed with cation-exchange HPLC (Fig. 7) The produced anti-IgE antibody is not specific for a definite allergen-induced IgE. It binds to any IgE in human blood and on cells.

5.3.2. Pharmacology and Effect of Omalizumab

There are four effects of omalizumab [149, 149 – 152]:

1) Omalizumab binds to the Cε3 domain of the IgE molecule which aggregates with the high-affinity receptor on mast cells and basophils. Thus the binding of the IgE molecule to the cell receptors is blocked and the release of mediators inhibited. Omalizumab does not interact with already bound IgE on FcεR receptors, therefore no degranulation or forming of mediators will be induced.
2) Omalizumab binds to the free IgE and forms molecular complexes. The relation of the free IgE to the concentration of omalizumab determinates the forming of trimers or hexamers (Fig. 8). The molecular complexes will have a molecular weight from 490 to 1000 kD. The application of omalizumab immediately leads to a reduction of the free IgE, but the values of total IgE, which include the measuring of the complexes will rise. The complexes have no pathogenic meaning. The most important step for suppressing the allergic reaction is the decrease of the free IgE.
3) Under the treatment with omalizumab the number of receptors on basophils and mast cells decreases significantly. Thus the capacity of IgE binding is reduced. This effect will last for several months.
4) Omalizumab plays also an important role in immunomodulation. The number of receptors on other cells involved in the allergic reaction such as tissue and dendritic cells decreases as well. This effect will have a long-lasting suppression of the induction and stimulation of the T_H2 response. Recent work showed significant reduction of nasal and bronchial eosinophils, bronchial mast cells, T cells, and B cells [149].

Though the free IgE decreases immediately after application of omalizumab the clinical effect will only occur after several weeks. In all treated allergic individuals a release of symptoms will be achieved within 16 weeks. The efficacy of omalizumab is only warranted under application of the dose, symptoms of allergic disease will relapse after end of therapy.

5.3.3. Pharmacokinetics

The humanizing of the murine antibody assures immunogenic tolerance by the human immune system. The average absolute bioavailability of omalizumab after subcutaneous administration is 62 %. In a clinical study of adults with allergic rhinitis omalizumab was slowly absorbed after subcutaneous administration of 0.15 mg/kg and resulted in peak serum concentrations of 2 mg/L after 14 days. The substance is cleared slowly from circulation, with a mean $\pm$S.D. apparent clearance of 2.4$\pm$1.1 mL/L/kg/d, resulting in a terminal elimination half-life of one to four weeks [150]. Omalizumab has an IgG structure and is delayed eliminated by the reticuloendothelial system of liver endothel cells. The half-life of omalizumab will be 19 to 22 days on average. After withdrawal of omalizumab the former IgE level will be reached within 12 months [149]. There is no rebound effect. The IgE – omalizumab complexes are not pathogenic, they do not accumulate in the kidney and they do not bind complement.

5.4. Indication for the Teatment with Omalizumab, Guidelines for Use

Immunoglobulin E plays a key role in allergic diseases. Omalizumab offers the opportunities to stop the cascade of the allergic reaction in a very early stage. Omalizumab inhibits the early and late reaction of inflammation. There might be a wide range of indications but till now mainly the treatment of patients with allergic asthma and rhinitis [149, 152] has been evaluated in studies. In spite of full therapy there remain worldwide about 26 % (Europe) to 42 % (UK) of patients with insufficient or bad controlled asthma. Those instable patients are at an increased risk of hospitalization, visits in emergency rooms or asthma death. In several studies including

patients with medium or severe asthma omalizumab reduced significantly exacerbations and hospitalization, the dose of additional inhalant glucocorticosteroids could be decreased [153, 154]. Omalizumab was found to be an effective add-on therapy for difficult-to-treat asthma patients, who have an important unmet medical need despite best available therapy. Quality of life ameliorated significantly [155]. The efficacy of omalizumab was the better the severe the degree of asthma [149, 153, 154].

The recommendation of the EMEA [156] for the registration of omalizumab follows the indications approved till present:

→ Omalizumab is indicated as add-on therapy in adult and adolescent patients (12 years of age and above) with severe persistent allergic asthma who have a positive skin test or in vitro reactivity to a perennial aeroallergen and who have reduced lung function ($FEV_1 < 80\,\%$) as well as frequent daytime symptoms or nighttime awakenings and who have had multiple documented severe asthma exacerbations despite daily high-dose inhaled corticosteroids, plus a long-acting inhaled beta-2 agonist.
→ Omalizumab treatment should only be considered for patients with convincing IgE-mediated asthma
→ It is proposed that omalizumab is initiated by physicians experienced in the diagnosis and treatment of severe persistent asthma

5.5. Application, Dosage, Costs

The concentration of the free IgE has to fall under 20.8 IU/mL (50 ng/mL) before expecting any clinical effect. Omalizumab has to be given in a relation of 15 to 20:1 to the absolute number of IgE molecules. Before starting treatment the needed omalizumab concentration is measured out of the total IgE concentration and the body weight. The dosage has to be determined individually for each patient, at least 0.016 mg/kg/IgE [IU/mL] every four weeks [150]. The maximum dosage is 750 mg every four weeks. The dosage is limited to a maximum of 700 kU/mL IgE and to a maximum body weight of 130 kg, because in these cases the calculated amount of the substance can no more be injected. The substance is supplied as a lyophilized sterile powder in a single-use, 5-mL vial designed to deliver 150 mg (1.2 mL) of drug after reconstitution. The lyophilized product takes about 15 – 20 min to dissolve while shaking the vial. The prepared solution should be used within eight hours when stored in the vial at 2 – 8 °C or within four hours when stored at room temperature. Reconstituted omalizumab is for single use only, it contains no preservatives. The recommended dosage per injection ranges between 150 mg and 375 mg omalizumab every two to four weeks according the necessary amount of the substance. The substance has to be given subcutaneously. More than one injection site should be used if the dosage exceeds 150 mg [150]. Total IgE levels remain elevated approximately for up to one year after ending of treatment. Dosage determination during therapy has always to be based on the initial IgE level. Significant changes in body weight must be taken into account. Omalizumab costs about 540 dollars (460 €) per vial, for a one-year therapy a sum of about 6000 to 10 000 dollars will be estimated. Yet evaluating this sum one has to consider that 5 to 10 % percent of patients with the most severe form of asthma contribute some 50 % of the total costs associated with asthma [157].

5.6. Side Effects

Placebo controlled studies have shown a very good tolerability of omalizumab. In a study with children occurred mainly urticaria (1.3 %), itching, rash, and pain on the site of the injection

Figure 8. Omalizumab-IgE complexes. With courtesy of Novartis.

(each 0.4 %) [158]. In several controlled studies with adults there were no differences in adverse events between the omalizumab and control groups [149]. Till present in clinical studies three not severe anaphylactic reactions (< 0,1 % of treated patients) were observed. Symptoms were urticaria, throat, or tongue edema [150]. There are no special substance related severe side effects. The IgE–omalizumab complexes are small, no serum sickness or immune complex nephropathy will be induced. A small percentage (< 0,1 %) of patients may develop antibodies to omalizumab.

5.7. Legal Aspects, Safety

Omalizumab is currently approved for moderate-to-severe persistent allergic asthma in the USA, Canada, and Brazil, for moderate persistent allergic asthma in Australia, and for severe persistent allergic asthma in New Zealand [149]. Till the end of 2005 omalizumab will be registered in Germany. The official use of the substance is restricted for definite criteria following the guidelines (Section 5.4). Detailed conditions for the use of this product will be described in the Summary of Product Characteristics (SPC) which will be published in the European Public Assessment Report (EPAR) and will be available in all official European languages after the marketing authorization has been granted by the European Commission [156]. The Global Initiative for Asthma (GINA) recommends treatment with omalizumab in her recent guidelines [148]. Because of the limited data regarding the safety and effectiveness in children, the official use of omalizumab is recommended for patients 12 years of age or older. Safety and efficacy have not been established for patients with a body weight or a serum IgE outside the recommended range. During pregnancy omalizumab should only be applied when clearly needed. In breast-feeding women caution is recommended, because in animal studies omalizumab was excreted in the milk [150].

5.8. Possible Applications in the Future

Omalizumab is an innovative and unique form of treatment, because it offers preventive therapy of IgE-mediated disorders. Future aspects for indication with omalizumab could be seasonal allergic airways disease, atopic eczema with high IgE values, venom allergy, food allergy, and desensitization in high-reactive patients. In a study of patients with peanut allergy the treatment with anti-IgE (TNX-901, similar to omalizumab) gave a protection against small amounts of unintended ingestions of peanuts [159]. The therapy will not be given widespread because of the relatively high costs, but further experiences will be gathered within the next years. Omalizumab will surely offer new interesting perspectives of antiallergic therapy.

1. Antiarrhythmic Drugs

1.1. Physiology

Unimpaired functioning of the heart is the most important requirement for the normal supply of blood to all regions of the organism. The heart rhythm is determined by the body's changing requirements for blood. This constant adjustment is controlled by venous return from the body's periphery, which influences both the stroke volume of the individual heart beats and the contractile force of the ventricular muscle. Heart rate and contractile force are controlled by the autonomic nervous system.

The individual heart beat begins with the electrical excitation of the *sinoatrial node* (SA node), a group of special pacemaker cells situated at the entrance of the superior vena cava. The SA node generates impulses automatically; their frequency is controlled largely by the autonomic nervous system, although it also can be affected by hormones, e.g., adrenaline, by metabolic processes, and by wall tension. The normal frequency of SA node excitation is about 70 – 80 impulses per minute. Within the heart, excitation spreads via the conduction system from the SA node to the atrial muscles and also to the atrioventricular node, passes through it, and travels along special fibers within the ventricular walls (*His-Purkinje system*), thereby reaching the ventricular muscle (working myocardium).

The *atrioventricular node* (AV node) is a secondary pacemaker; its natural frequency is lower than that of the SA node (its intrinsic rhythm is about 40 – 60 impulses per minute). Accordingly, the higher frequency of the SA node determines the normal heart beat. However, if the SA node fails, the AV node can take over the pacemaker function. A similar relationship exists between the AV node and the Purkinje fibers. They also are capable of spontaneous rhythmic activity if the AV node fails; however, their frequency is at 15 – 40 impulses per minute.

Contraction of the heart muscle therefore is the result of electrical, biochemical, and mechanical processes in the cell membranes and within the myocardial cells (electromechanical coupling). Blood is pumped by the contraction of the heart wall muscles in coordination with the functioning of the various heart valves. All processes associated with the excitation and contraction of the heart are reversible. All the abovementioned phenomena and the automaticity of the pacemakers, particularly the SA node, therefore enable the heart to function rhythmically. For more information on the physiology of excitation and contraction of the heart, see [1–4].

1.2. Disorders of Cardiac Rhythm (Arrhythmias)

Diagnosis. Arrhythmias differ greatly in their etiology and symptoms. The most important diagnostic tool is the *electrocardiogram* (ECG).

The electrocardiogram reflects electrical potential changes in the heart as a function of time. The potential differences originate from the so-called "action potentials" at all excitable cardiac cells (see Section 1.3); they are measured at various sites on the body's surface. For example, the ECG in Figure 1 has been obtained from electrodes placed on the right arm and the left leg. A series of waves, designated P, Q, R, S, and T, is detected. The P – Q interval is the period between the beginning of the contraction of the atria and the beginning of the contraction of the ventricles. The QRS complex is caused by the depolarization of the ventricles. The Q – T interval reflects the duration of ventricular contraction.

A more accurate diagnosis of cardiac arrhythmias is made possible by *His bundle electrography.* In this method, the electrical activity of the heart is detected by intracardiac electrodes, which are inserted intravenously [5], [6]. In addition, intermittent arrhythmias may be detected by *24-hour long-term electrocardiography* (Holter monitoring) [7]. In certain types of arrhythmias, auscultation of the heart sounds as well as palpation of the pulse in arteries and neck veins also provide information on the presence and type of arrhythmia.

Arrhythmias are classified in two main groups according to their etiology: disorders of impulse generation and disturbances of impulse conduction.

Disorders of Impulse Generation. *Nomotopic disorders* involve the normal pacemaker, i.e., the sinoatrial node. They occur either as *sinus tachycardia* (increased rate) or *sinus bradycardia* (reduced rate). Irregular functioning of the sinus node also may cause sinus arrhythmias. Impulse generation disorders are called *heterotopic* when the impulse originates not in the sinoatrial node but in one of the centers subordinate to it: in the AV node, at certain foci in the ventricular conduction system with escape rhythms, or even at other sites of the heart muscle. They trigger individual, premature heart beats, which are called *extrasystoles.* These may occur either sporadically or frequently, irregularly or firmly coupled to the normal rhythm of the heart. *Polytopic extrasystoles* originate at several different foci simultaneously. Depending on the anatomic position of the impulse generation, extrasystoles are described as supraventricular or ventricular. *Supraventricular extrasystoles* are triggered at points above the His-Purkinje system. They include sinoidal, atrial, and atrioventricular extrasystoles. *Ventricular extrasystoles* originate in the His-Purkinje system or in the ventricular myocardium.

Paroxysmal Tachycardia. Heterotopic disorders of impulse generation also include sudden and more or less prolonged phases of a highly accelerated heart rate, which are known as paroxysmal tachycardias. Rapid regular impulse generation (250 – 300/min) in the atrium is known as *atrial flutter.* In this case, impulse conduction to the ventricles is disturbed. The same applies to *atrial fibrillation,* which is characterized by high-frequency ($>$ 400/min) and irregular impulse generation. Because the ventricles may be refractory to most of these impulses, their activity becomes irregular; this results in *absolute arrhythmia.*

Similar impulse-generation disorders may also originate in the ventricles, namely *ventricular flutter* (with a frequency in most instances above 220/min) and *ventricular fibrillation* in which irregular multifocal impulses occur simultaneously at high frequency. In ventricular flutter, the heart is still able to pump a small volume of blood; in ventricular fibrillation, however, circulatory arrest occurs.

Impulse-Conduction Disturbances. Impulse transmission to lower sections of the heart can be delayed or blocked at different points of the conduction system. Atrial or ventricular systoles can be blocked either partially or completely. In *total sinoatrial block,* sinus excitation does not reach the atria and the ventricles at all. Consequently, systoles cease until another pacemaker situated at a lower level becomes active as the automaticity center.

Intra-atrial disturbances affect impulse propagation within the atrial musculature. They

Figure 1. Normal ECG with bipolar recording from the body surface in the direction of the long axis of the heart
The times below the ECG curve are important limiting values for the durations of the parts of the curve [1].

are less significant provided regular conduction to the ventricles remains intact.

However, *atrioventricular block* (AV block), in which conduction between atria and ventricles is disturbed, is extremely important. Atrioventricular block is characterized according to either location or degree. In *first-degree AV block,* conduction is still regular but in some cases delayed by several times the normal duration. In *second-degree AV block* (incomplete AV block), conduction is interrupted sporadically or frequently. In *third-degree AV block* (total heart block) there is no conduction of excitation between atria and ventricles. Both beat independently of one another, the atria generally at the sinus rate and the ventricles about once every two seconds.

In *intraventricular disturbances,* impulse conduction within the ventricular walls is delayed or interrupted.

For more detailed information on causes and basic diseases, syndromes, diagnosis, therapy, and prognosis of cardiac arrhythmias, see [5–7], [9].

1.3. Cardiac Action Potentials

In the heart, as in other excitable tissue, rest and excitation are accompanied by electrical phenomena, the so-called action potentials, which are caused by ionic currents. The flow of ions into and out of the cardiac cells is controlled by changes in cell membrane permeability to sodium, potassium, and calcium ions. For details, see [1–4], [6–9].

Figure 2 shows transmembrane action potentials of normal, nonautomatic cardiac cells, such as ventricular or atrial muscle cells (V), and of sinoatrial nodal cells (SA). Usually, five different phases are distinguished [10].

In *phase 0* rapid depolarization occurs on excitation. The difference in membrane potential decreases and the inside of the cell becomes positive in relation to the outside during the so-called overshoot. The ionic mechanism for phase 0 is an increase in sodium conductance.

Figure 2. Action potentials of a ventricular muscle cell (V) and a sinoatrial nodal cell (SA).
TP = Threshold potential

The first phase of repolarization (*phase 1*) is quite rapid and is followed by a period of slow repolarization (*phase 2* or plateau). Repolarization speeds up again in *phase 3* and completes the process by returning the transmembrane potential to the resting potential. The ionic mechanisms for repolarization are an increase in calcium conductance (slow inward flow) and a decrease in potassium conductance. In ventricular muscle cells, *phase 4* is characterized by an electrical quiescence in which depolarization currents and repolarization currents are in balance.

The action potentials of automatic cells, such as those of the sinoatrial node, differ conspicuously from those of ventricular muscle cells: First, the maximum diastolic potential reached in these cells is less negative (−70 mV). Second, the automatic SA nodal cells exhibit spontaneous diastolic depolarization. This is shown by the gradual increase of transmembrane action potential in phase 4. When the potential difference reaches the threshold potential (TP; about −50 mV in SA nodal cells), rapid depolarization (phase 0) occurs. This mechanism, by which the heart generates its own impulse, is called autorhythmicity. Finally, upstroke velocity (phase 0) and amplitude are distinctly smaller.

Further parameters of the transmembrane action potential that are important in a discussion of the mechanism of action of antiarrhythmic drugs are:

1) *Action potential amplitude:* the total potential change occurring during phase 0
2) *Action potential duration* (APD): the period from the start of phase 0 to the end of phase 3
3) *Conduction velocity:* the speed at which a stimulus or action potential is propagated
4) *Automaticity:* determined by the slope of phase 4 (discussed previously)
5) *Maximum upstroke velocity* (V/s): the steepest slope of rise during phase 0
6) *Excitability:* dependent on the level of the threshold potential
7) *Effective refractory period* (ERP): period of repolarization during which no normal action potential can be elicited, although a weak, nonpropagated action potential can arise
8) *Relative refractory period* (RRP): period of repolarization in which no propagated action potential can arise

These parameters can be altered experimentally by antiarrhythmic drugs. The therapeutic antiarrhythmic activity of such drugs in humans is associated with these changes also.

The most important antiarrhythmics are those that inhibit pathologically accelerated impulse generation and/or propagation, that is, any so-called *tachyarrhythmia.* Such compounds are also termed *antifibrillatory drugs.*

Bradyarrhythmias are disturbances of cardiac rhythm caused by delayed or blocked impulse generation and/or propagation; they are rare. The bioelectrical phenomena of heart function insure that the heart always responds to the more rapid pacemaker. Whenever impulse generation in the SA node is delayed, normal cardiac function can be restored by implanting an *electrical pacemaker.* In emergencies, but not in long-term therapy, sympathomimetic noradrenaline and parasympatholytic atropine can be administered parenterally. Oral β-sympathomimetics, such as isoprenaline and orciprenaline, may be used until a pacemaker is implanted.

1.4. General Aspects of Pharmacology

Antiarrhythmic agents act by changing the electrical properties of the membrane of the heart cell [11].

Figure 3 shows the characteristic changes caused by various class I antiarrhythmic agents in the ventricular action potential (Fig. 3 A), the electrocardiogram (Fig. 3 B), the duration of the effective refractory period (ERP), the relative refractory period (RRP), and the total action potential duration (APD; Fig. 3 C).

Figure 3. Effects of various antiarrhythmic drugs on the ventricular action potential, the electrocardiogram, and the durations of the effective refractory period (ERP), the relative refractory period (RRP), and the total action potential duration (APD) [11].
The arabic numerals in parentheses indicate phases of the action potential1.3. The circles represent the level of repolarization at which the fiber becomes reexcitable.

The classification of antiarrhythmic agents by Vaughan Williams [12–14] (Table 1), is comprised of four classes and three subgroups of class I; it is based primarily on electrophysiological effects (class II is the exception).

Several of the drugs act in more than one of the four ways; therefore, the classification does not so much categorize the agents as it describes four ways in which abnormal cardiac rhythms can be corrected or prevented.

Class I: Sodium Channel Blockers. All class I antiarrhythmic agents (I a, I b, and I c) decrease the rate of rise (upstroke velocity) of phase 0 of the action potential by inhibiting the rapid sodium influx. Under suitable conditions these agents also can block the sodium channels of nerve fibers, which explains the local-anesthetic effect of class I agents.

Under block, the sodium channels may recover quickly or slowly, depending on the class of antiarrhythmic drug [15]. With *class I b agents,* such as lidocaine, phenytoin, tocainide, mexiletine, or sparteine, recovery time is less than 1 s. Therefore, this class of drugs can block premature and high-frequency excitation selectively. With *class I a* or *class I c agents,* however, the recovery time of the sodium channels is longer (1 – 250 s); therefore, the blocking effect also affects normal-frequency action potentials. This difference also is detected by ECG. In the healthy heart, class I b antiarrhythmic agents in therapeutic doses do not change the conduction times, whereas class I a and class I c agents

Table 1. Classification of antiarrhythmic drugs [14] , pp. 232, 234 [15]

	Generic name	Mode of action	ECG changes ∗			
			Heart rate	P–Q ∗∗ interval	QRS ∗∗ duration	Q–T ∗∗ interval
Class I a:	quinidine procainamide disopyramide	sodium channel blockade by classes I a, I b, I c; rate of rise of phase 0	inc.	(inc.) (dec.)	inc.	inc.
Class I b:	lidocaine phenytoin tocainide sparteine mexiletine	of action potential: delayed by I a, I b, I c; action potential duration: shortened by I b, not changed or prolonged	dec.	-	-	-
Class I c:	ajmaline prajmalium aprindine lorcainide flecainide propafenone	by I a and I c	dec.	inc.	inc.	-
Class II:	propranolol and all other β-blockers	β-receptor blockade	dec.	inc.	-	-
Class III:	amiodarone sotalol bretylium	prolongation of action potential duration	dec.	-	-	inc.
Class IV:	verapamil gallopamil diltiazem bepridil	calcium channel blockade; action potential (SA node and AV node) duration and plateau shortened	dec.	inc.	-	-

∗ dec., decrease; inc., increase; -, no or little change; ( ), change not pronounced.
∗∗ for definition, see 1.2.

lengthen the ECG times (Fig. 3). Some class I a agents have an additional atropine-like effect. Occasionally this increases frequency and shortens the P – Q interval.

The duration of the action potential and the Q – T interval in the ECG are lengthened by class I a agents (quinidine, procainamide, disopyramide) and by some class I c agents (ajmaline, propafenone) but are shortened by class I b agents (phenytoin, lidocaine, mexiletine). Phenytoin acts during repolarization: the membrane potential at which the fibers become reexcitable is shifted to a more negative value and the effective refractory period is lengthened with respect to total action potential duration.

Class II: β-Receptor Blocking Agents. Two types of receptors exist in the sympathetic nervous system: α- and β-receptors [16]. Stimulation of β-receptors produces increased sympathetic activity of the heart, increasing contractility, oxygen consumption, and heart rate and accelerating impulse propagation.

These effects are specifically, competitively, and reversibly blocked by β-receptor blockers. In addition to this specific effect, high doses of β-blockers also block membrane sodium channels (membrane stabilizing effect). In antiarrhythmic therapy, β-blockers are used primarily for tachyarrhythmias resulting from sympathetic hyperfunction or from increased catecholamine release [17] (→ β-Receptor Blocking Agents).

Class III: Agents That Increase Action Potential Duration. Class III antiarrhythmic agents lengthen the duration of the action potential without changing its rate of rise. The refractory period of the heart fibers is therefore prolonged. Currently, only three agents of this class are known: amiodarone, sotalol, and bretylium.

Class IV: Calcium Channel Blockers. Calcium channel blockers also are known as calcium antagonists. In various excitable cells these agents block the slow influx of calcium ions through the cell membrane during excitation; the flow of sodium ions is not influenced. Calcium antagonists are applied chiefly in coronary heart disease. Some of these substances also are used in antiarrhythmic therapy: verapamil, gal-

lopamil, diltiazem, and bepridil. Their antiarrhythmic effect is based on prolongation of the impulse conduction in the AV node and to a lower degree on inhibition of the impulse generation in the sinus node. They act especially on tachyarrhythmias that originate in the atria (see also → Calcium Antagonists).

1.5. General Aspects of Chemistry

Class I antiarrhythmic agents belong to two groups: N-substituted carboxamides and ajmaline derivatives. The group of N-substituted carboxamides includes lidocaine, tocainide, procainamide, disopyramide, lorcainide, flecainide, bunaftine, and encainide; mexiletine usually is included because of its similar structure. Antiarrhythmic drugs of the second group include the ajmaline-type alkaloids and such derivatives as prajmalium, detajmium, and lorajmine, as well as quinidine and sparteine. Some other substances, e.g., phenytoin and aprindine, do not fit into either group.

All N-substituted carboxamides have three features in common: a lipophilic aromatic group, an aliphatic spacer group, and an amino substituent. *Lipophilicity* is crucial for nonspecific interaction with the alkyl chains of the membrane's phospholipids. Together with the amino group, which can be protonated at physiological pH values, this seems to be the molecular requirement for antiarrhythmic activity in this group of compounds. The molecular interaction between these drugs and the membrane and quantitative structure – activity relations of antiarrhythmic agents are described in more detail in [18].

The class II antiarrhythmic agents (β-receptor blockers) virtually all belong to the group of aryloxyaminopropanols (→ β-Receptor Blocking Agents). As mentioned above, these compounds can even initiate a membrane-stabilizing effect if administered in relatively high concentrations. Predominantly the L-isomers of the β-receptor blockers show β-adrenolytic activity; the membrane-stabilizing effect is observed in both isomers and depends on the lipophilicity of the compounds [19], [20].

Structure – activity relationships are not evident in class III and class IV antiarrhythmic agents.

2. Individual Antiarrhythmic Drugs

[6], [7], [9], [15], [21–24]

2.1. Class I Drugs: Sodium Channel Blockers

2.1.1. Class I a Drugs

Quinidine [*56-54-2*], (+)-(αS)-α-(6-methoxy-4-quinolyl)-α-[(2*R*,4*S*,5*R*)-(vinylquinuclidin-2-yl)]methanol, $C_{20}H_{24}N_2O_2$, M_r 324.4, *mp* 174 – 175 °C.

Quinidine is one of the most widely applied antiarrhythmics and has been used for 30 years. It is used primarily against atrial flutter and fibrillation and against heterotopic extrasystoles.

Quinidine generally is administered orally, although slow intravenous administration also is possible [25]. Quinidine is the prototype of class I antiarrhythmics; therefore, substances in this group also are called "quinidine-like." However, it differs, for example, from lidocaine by the following effects: it increases the duration of the action potential, in the ECG it increases QRS duration and Q – T interval, and the refractory period is markedly prolonged. Quinidine can accelerate the impulse conduction rate in the AV node (atropine-like effect). Side effects include gastrointestinal disturbances and allergic reactions.

Trade Names: Chinidin, Kinidin (Astra Chemicals) contain quinidine hydrogen sulfate [*747-45-5*]; Duraquin (Parke-Davis), Quinaglute (Berlex) contain quinidine gluconate [*7054-25-3*].

Procainamide [*51-06-9*], 4-amino-*N*-(2-diethylaminoethyl)benzamide, $C_{13}H_{21}N_3O$, M_r 235.3; the hydrochloride [*614-39-1*] melts at 165 – 169 °C.

In the United States procainamide is one of the most frequently used antiarrhythmics; in Europe, it is of minor importance. Its mode of action resembles that of quinidine. The substance may be administered parenterally and orally but is only short acting. Side effects with longterm therapy are gastrointestinal disturbances, agranulocytosis, and lupus erythematosus. An antiarrhythmic metabolite, acecainide page 13, was detected in humans.

Trade Names: Novocamid (Hoechst), Pronestyl (Squibb) both contain procainamide hydrochloride.

Disopyramide [*3737-09-5*], (±)−4-diisopro-pylamino-2- phenyl-2- (2-pyridyl) butyramide, $C_{21}H_{29}N_3O$, M_r 339.5, *mp* 94.5 °C.

Disopyramide has a pharmacological profile similar to that of quinidine and procainamide [26–29]. Clinically, it is active against most forms of arrhythmias (supraventricular and ventricular). However, the substance also can produce serious side effects, such as negative inotropic and hemodynamic effects, increased oxygen consumption, and increased infarct size, as well as anticholinergic activity.

Trade Names: Norpace (Searle), Rythmodan (Roussel), Rythmodul (Albert Roussel), all contain disopyramide phosphate [*22059-60-5*].

2.1.2. Class I b Drugs

Lidocaine [*137-58-6*], lignocaine, *N*-(2,6-xylyl)-diethylaminoacetamide, $C_{14}H_{22}N_2O$, M_r 234.4, *mp* 68 – 69 °C.

Lidocaine is used both as a local anesthetic and as an antiarrhythmic. As an antiarrhythmic it is administered only parenterally as an infusion because it has a short half-life. The most important side effects are disturbances of the central nervous system.

Trade Names: Xylocain, Xylocaine, Xylocard (Astra Chemicals); all preparations contain lidocaine hydrochloride [*73-78-9*].

Phenytoin [*57-41-0*], 5,5-diphenylhydantoin, $C_{15}H_{12}N_2O_2$, M_r 252.3, *mp* 295 – 298 °C.

Phenytoin is used primarily as an antiepileptic. The compound finds its chief use as an antiarrhythmic in cases of cardiac glycoside overdosage. The effect of the substance is difficult to control because of its long half-life. In addition, it has strong cardiac and extracardiac side effects (gingival hyperplasia, osteomalacia, anemia, hypertrichosis).

Trade Names: Dilantin, Epanutin (Parke Davis), Phenydan (Desitin), Zentropil (Nordmark-Werke); all preparations contain phenytoin sodium [*630-93-3*].

Tocainide [*41708-72-9*], (±)−2-amino-*N*-(2,6-xylyl)propionamide, $C_{11}H_{16}N_2O$, M_r 192.1; the hydrochloride [*35891-93-1*] melts at 246 – 247.5 °C.

Tocainide corresponds to lidocaine in its action profile and side effects. In contrast to lidocaine it can be taken orally because it lacks two ethyl groups that contribute to lidocaine's first-pass hepatic degradation after oral administration [27], [30], [31]. The substance has been on the market in most European countries since 1981 – 1982.

Trade Names: Tonocard, Xyloctan (Astra Chemicals); all preparations contain tocainide hydrochloride.

Mexiletine [*31828-71-4*], (±)-1-methyl-2-(2,6-xylyloxy)ethylamine, $C_{11}H_{17}NO$, M_r 179.3; the hydrochloride [*5370-01-4*] melts at 203 – 205 °C.

Mexiletine is effective both parenterally and orally [32], [33]. Because the substance has a large distribution volume, a high initial dose is necessary. Side effects include bradycardia and disturbances of the central nervous system.

Trade Name: Mexitil (Boehringer Ingelheim) contains mexiletine hydrochloride.

Sparteine [*90-39-1*], dodecahydro-7,14-methano-2*H*, 6*H*-dipyrido-[1,2-*a* : 1′,2′-*e*][1,5]diazocine, $C_{15}H_{26}N_2$, M_r 234.4, *bp* 173 °C (at 11 kPa).

Sparteine is effective against sinoatrial and atrial tachycardias, atrial extrasystoles, and also against ventricular arrhythmias [34]. Despite prolongation of the myocardial refractory period in vitro, the ECG times are not prolonged in vivo.

Pregnancy in the last trimester is a contraindication because the substance can induce labor through increased smooth muscle tone.

Trade Name: Depasan (Giulini) contains sparteine sulfate [*299-39-8*].

2.1.3. Class I c Drugs

Ajmaline [*4360-12-7*], (17*R*,21*R*)-ajmalan-17,21-diol, $C_{20}H_{26}N_2O_2$, M_r 326.4, *mp* 195 °C (decomp.).

Ajmaline is active against both ventricular and supraventricular arrhythmias [35–37]. Unlike quinidine, procainamide, and disopyramide, ajmaline has no anticholinergic activity and shows only a weak negative inotropic effect. The preferred route of application is slow intravenous infusion because oral bioavailability varies greatly among individuals. Side effects include disturbances of the central nervous system and intrahepatic cholestasis.

Trade Names: Cardiorythmine (Servier), Gilurytmal (Giulini).

Prajmalium bitartrate [*2589-47-1*], 4-propylajmalium hydrogen tartrate, $C_{27}H_{38}N_2O_8$, M_r 518.6, *mp* 133 °C (decomp.).

With at least five times the potency of ajmaline, prajmalium is a most effective antiarrhythmic, and it is superior to ajmaline in its reliable oral effect and sustained action [37–39]. The activity profile of prajmalium is very similar to that of ajmaline, although the sodium channels are blocked much longer by it than by any other class I antiarrhythmic [15].

Trade Name: Neo-Gilurytmal (Giulini).

Detajmium bitartrate [*53862-81-0*], 4-(3-dimethylamino-2-hydroxypropyl)ajmaline hydrogen tartrate, $C_{31}H_{47}N_3O_9$, M_r 605.7, *mp* 123 – 125 °C.

Detajmium is comparable to ajmaline but shows better oral activity. In potency it ranges between ajmaline and prajmalium [40].

Trade Name: Tachmalor (VEB Arzneimittelwerk, Dresden).

Aprindine [*37640-71-4*], *N*-(3-diethylaminopropyl)-*N*-indan-2-ylaniline, $C_{22}H_{30}N_2$, M_r 322.5; the hydrochloride [*33237-74-0*] melts at 120 °C.

Aprindine has a sustained activity. Because of serious side effects (agranulocytosis), aprindine should only be used for life-threatening arrhythmias otherwise refractory to therapy [27].

Trade Names: Amidonal (Madaus), Fibocil (Lilly), Fiboran (Christiaens); all preparations contain aprindine hydrochloride.

Lorcainide [*59729-31-6*], 4′-chloro-*N*-(1-isopropyl-4-piperidyl)–2-phenylacetanilide, $C_{22}H_{27}ClN_2O$, M_r 370.9; the hydrochloride [*58934-46-6*] melts at 263 °C.

Like lidocaine, lorcainide acts primarily on ventricular arrhythmias but is stronger and also orally effective [41], [42]. Side effects include insomnia and gastrointestinal disturbances.

Trade Name: Remivox (Janssen) contains lorcainide hydrochloride.

Flecainide [*54143-55-4*], (±)-*N*-(2-piperidylmethyl)–2,5-bis-(2,2,2-trifluoroethoxy)benzamide, $C_{17}H_{20}F_6N_2O_3$, M_r 414.4; the hydrochloride [*54143-55-4*] melts at 228 – 229 °C.

Flecainide is effective if administered intravenously and orally; its effect is long-lasting. The drug combines the modes of action of class I a and I b drugs with those of class III. Flecainide shows few side effects; it does not affect the central nervous system [29], [43]. The substance has been used increasingly since it was first put on the market in 1982.

Trade Name: Tambocor (Kettelhack Riker) contains flecainide acetate [*54143-56-5*].

Propafenone [*54063-53-5*], (±)–2′-(2-hydroxy-3-propylaminopropoxy)–3-phenylpropiophenone, $C_{21}H_{27}NO_3$, M_r 341.5; the hydrochloride [*34183-23-8*] melts at 173 – 174 °C.

Propafenone has not only pronounced class I effects but also class II (structure related) and class IV activities [44–46]. Accordingly, it has a broad spectrum of activity against ventricular and supraventricular arrhythmias. Propafenone can be administered intravenously and orally; it is well suited for long-term anitiarrhythmic treatment [9] and has been increasingly used since it was first marketed in Germany in 1978.

Trade Name: Rytmonorm (Knoll) contains propafenone hydrochloride.

2.2. Class II Drugs: β-Receptor Blocking Agents

For more information, → β-Receptor Blocking Agents.

Propranolol [*525-66-6*], (±)–1-isopropylamino-3-(1-naphthyloxy)-propan-2-ol, $C_{16}H_{21}NO_2$, M_r 259.3; the hydrochloride [*318-98-9*] melts at 163 – 164 °C,

Major indications of propranolol, and of many other β-blockers, include coronary heart disease, hypertension, and cardiac arrhythmias. These β-blocking agents are mainly used in arrhythmias accompanied by increased catecholamine levels, e.g., excitement, stress, or hyperthyroidism [17].

Trade Names: Dociton, Inderal (ICI) contain propranolol hydrochloride.

2.3. Class III Drugs: Agents Increasing the Action Potential Duration

Amiodarone [*1951-25-3*], (2-butylbenzofuran-3-yl)-[4-(2-diethylaminoethoxy)−3,5-diiodophenyl]ketone, $C_{25}H_{29}I_2NO_3$, M_r 645.3; the hydrochloride [*19774-82-4*] melts at 161 °C.

Amiodarone was introduced as a coronary therapeutic agent more than 20 years ago. Later, its antiarrhythmic activity was discovered [47–49]. Amiodarone increases the duration of the refractory period and is active against supraventricular as well as ventricular arrhythmias. Its therapeutic spectrum is relatively broad. The full activity of amiodarone only develops after 10 – 15 d of treatment. The drug is active up to 45 d after it is discontinued. Side effects include: microcrystalline deposits in the cornea in 90 % of the cases, impaired thyroid function, and photosensitivity.

Trade Names: Cordarex, Cordarone (Labaz), both contain amiodarone hydrochloride.

Sotalol [*3930-20-9*], (±)−4′-(1-hydroxy-2-isopropylaminoethyl)methanesulfoanilide, $C_{12}H_{20}N_2O_3S$, M_r 272.4; the hydrochloride [*959-24-0*] melts at 207 °C.

Sotalol acts as an antiarrhythmic by β-receptor blockade as well as by prolonging the action potential duration in atrium and ventricle and the refractory period in atrium and AV node [48]. Activity against supraventricular and ventricular arrhythmias was demonstrated. The substance has the typical side effects of β-blockers.

Trade Names: Beta-Cardone (Duncan, Flockhart), Sotalex (Lappe), Sotazide (Bristol-Meyers Pharmaceuticals), all preparations contain sotalol hydrochloride.

Bretylium tosylate [*61-75-6*], 2-bromobenzyl (ethyl) dimethylammonium toluene-4-sulfonate, $C_{18}H_{24}BrNO_3S$, M_r 414.4, *mp* 97 – 99 °C.

Bretylium tosylate is reported to be effective in the acute control of recurrent ventricular tachycardia and even fibrillation [48], [50]. The drug is contraindicated in arrhythmias caused by digitalis intoxication.

Trade Names: Bretylol (American Critical Care), Bretylate (Wellcome).

2.4. Class IV Drugs: Calcium Channel Blockers

The main application of calcium antagonists is the treatment of coronary heart disease. The substances mentioned below also are active against arrhythmias.

Verapamil [*52-53-9*], (±)−5-[*N*-(3,4-dimethoxyphenethyl)-*N*-methylamino]−2-(3,4-dimethoxyphenyl)−2-isopropylvaleronitrile, $C_{27}H_{38}N_2O_4$, M_r 454.6; the hydrochloride [*152-11-4*] melts at 139.5 – 140.5 °C.

Verapamil, the classic calcium antagonist, has a negative inotropic, anti-ischemic, and conduction-delaying effect on the heart [27], [51–54]. Its antiarrhythmic effect is based primarily on a prolongation of impulse conduction time in the AV node and a reduction of frequency of impulse generation in the SA node. Verapamil has a very strong effect against paroxysmal supraventricular arrhythmias, although activity against ischemic ventricular arrhythmias has been demonstrated also [51]. The most important side effect is decreased blood pressure.

Trade Names: Isoptin (Knoll), Securon (Knoll Ltd.), Calan (Searle), Cardibeltin (Pharma Schwarz), Cordilox (Abbott); all preparations contain verapamil hydrochloride.

Gallopamil [*16662-47-8*], (±)−5-[*N*-(3,4-dimethoxyphenethyl)-*N*-methylamino]−2-(3,4,5-trimethoxyphenyl)−2-isopropylvaleronitrile, $C_{28}H_{40}N_2O_5$, M_r 484.7; the hydrochloride [*16662-46-7*] melts at 145 – 148 °C.

Gallopamil has a distinctly stronger effect than verapamil but a similar activity profile [54], [55].

Trade Name: Procorum (Chemische Werke Minden); contains gallopamil hydrochloride.

Bepridil [*74764-40-2*], *N*-(3-isobutoxy-2-pyrrolidin-1-ylpropyl)-*N*-phenylbenzylamine, $C_{24}H_{34}N_2O$, M_r 366.3; the hydrochloride monohydrate melts at 88 – 90 °C.

In addition to class IV effects, bepridil also shows class I effects. The substance is active against both supraventricular and ventricular arrhythmias [56], [57].

Trade Name: Cordium (Lab. Mauverney); contains bepridil hydrochloride monohydrate.

Diltiazem [*42399-41-7*], *cis*-(+)−3-acetoxy-5-(2-dimethylamino-ethyl)−2,3-dihydro-2-(4-methoxyphenyl)−1,5-benzothiazepin-4(5*H*)-one, $C_{22}H_{26}N_2O_4S$, M_r 414.5, *mp* 212 °C (decomp.).

Like verapamil and gallopamil, diltiazem has both vascular (antihypertensive) and cardiac (antianginal) activities and shows antiarrhythmic activity similar to these drugs [58], [59].

Trade Names: Dilzem (Gödecke), Herbesser (Tanabe), Cardizem (Marion); all preparations contain diltiazem hydrochloride [*33286-22-5*].

2.5. New Antiarrhythmic Drugs

Only limited clinical experience exists for these drugs.

Encainide [*37612-13-8*], (±)−2′-[2-(1-methyl-2-piperidyl)ethyl]-*p*-anisanilide, $C_{22}H_{28}N_2O_2$, M_r 352.2, *mp* 131.5 – 132.5 °C.

Encainide is a membrane-active class I c agent with complex metabolism and clinical pharmacology [60], [61]. To date, its effectiveness has been proved against ventricular arrhythmias. Side effects include central nervous system activity.

Trade Name: Enkade (Bristol-Meyers).

Bunaftine [*32421-46-8*], *N*-butyl-*N*-(2-diethylaminoethyl)-1-naphthamide, $C_{21}H_{30}N_2O$, M_r 326.7.

Bunaftine is said to have a "quinidine-like" effect.

Trade Name: Meregon (Malesci) contains bunaftine citrate.

Moracizine [*31883-05-3*], ethyl[10-(3-morpholinopropionyl)phenothiazin-2-yl]carbamate, $C_{22}H_{25}N_3O_4S$, M_r 427.5, *mp* 156 – 157 °C.

Moracizine is said to have an activity similar to but stronger than quinidine. Gastrointestinal and neurological side effects are observed rarely [27], [62].

Trade Name: Ethmozine (Riga Pharmaceutical "Alaine Pharm," USSR).

Lorajmine [*47562-08-3*], ajmaline-17-chloroacetate, $C_{22}H_{27}ClN_2O_3$, M_r 402.9.

In electrophysiological studies, lorajmine has been shown to exert a lidocaine-like (class I b) rather than an ajmaline-like (class I c) effect [63].

Trade Names: Ritmos Elle (Inverni della Beffa), Viaductor (Lab. Servier); both contain lorajmine hydrochloride [*40819-93-0*].

Acecainide [*34118-92-8*], 4-acetylamino-*N*-[2-(diethylamino)ethyl]benzamide, $C_{15}H_{23}N_3O_2$, M_r 315.65; the hydrochloride melts at 190 – 193 °C.

Acecainide, a main metabolite of procainamide, is a class I a antiarrhythmic agent [64].

Trade Name: Napa (Medco).

1. Introduction

Asthma therapy is based on the complex pathophysiology of this disease. Because of the variety of stimuli and the multiple factors that are involved in the induction and development of asthma, its treatment involves a multiplicity of therapeutic approaches and drugs [1], [2].

Bronchial asthma is generally understood to be a chronic inflammatory pulmonary disease characterized by recurrent episodes of wheezy labored breathing with prolonged expiration accompanied by dry coughing and tough mucus. These symptoms are the clinical expression of a narrowing of the bronchi (bronchoconstriction), a bronchial mucosal thickening (edema, eosinophilic bronchial infiltration), bronchial wall remodeling, and an excessive mucus production with plugging of the conducting airways in the lungs. This more or less generalized airway changes result in an increased irritability or sensitivity of the bronchi (bronchial hyperreactivity) to a wide variety of stimuli (irritants), allergic and nonallergic. The obstruction is usually reversible, either spontaneously or in response to appropriate therapy.

Depending on its dynamics bronchial asthma is clinically categorized into *acute* (attacks, status asthmaticus) and *chronic* (persistent) asthma. It is further subdivided into *extrinsic* and *intrinsic* asthma depending on the nature of its causes.

Extrinsic or allergic asthma (50 % of cases) generally occurs in childhood or young adulthood (under the age of 40) and relates to such extrinsic factors as common allergens (pollens, house dust, animal dander, inhalants, and some foods and drugs) or occupationally encountered dust (sawdust, flour). The house dust mite *Dermatophagoides pteronyssinus* is often involved. Extrinsic asthma can be controlled effectively with drug therapy.

Intrinsic or nonallergic asthma generally occurs in middle-aged patients who have no family history of allergies and exhibit negative allergy tests. It relates to intrinsic factors that are not well understood, e.g., respiratory tract infections, exercise, emotional stress, changes in weather and temperature, cold air, and inhalation of such air pollutants as sulfur dioxide and other chemicals, e.g., diisocyanates, poly(vinyl chloride), phthalic anhydride, or ethylenediamine. Patients with intrinsic asthma do not respond well to drug therapy and may progressively develop a chronic form of asthma.

Bronchial hyperreactivity, the fundamental feature of asthma, has been attributed to a pathophysiologic mechanism, which involves dysfunction of sympathetic nerves mediated by β-adrenergic receptors, hyperfunction of the parasympathetic nerves (efferent fibers of the vagus nerves), and altered intracellular cyclic adenosine monophosphate (cAMP) – cyclic

10.1002/14356007.a02_453

guanosine monophosphate (cGMP) ratios in bronchial smooth muscles (effector cells) or in mast cells [3–5]. Immunologic mechanisms (antigen – antibody reactions) also are involved. Remodeling of the bronchial wall due to the chronic inflammatory event may also contribute to airway hyperreactivity.

The smooth muscle of the airway is controlled by the autonomic nervous system and bronchoactive chemical mediators. The airways are supplied with both *sympathetic* and *parasympathetic* nerve fibers from the autonomic nervous system. At the bronchial smooth muscle preferentially β_2-adrenoreceptors mediate relaxation of the muscle, i.e., dilation of the bronchi. Stimulation of the parasympathetic nerve fibers (*Nervus vagus*) or the administration of acetylcholine causes bronchoconstriction.

The bronchial smooth muscle also responds to bronchoactive chemical mediators, including such bronchoconstrictors as histamine, serotonin, neurokinins, and prostaglandins (PG), e.g., PGF_{2a}. The leukotrienes C_4, D_4, and E_4, are also included in this group. Bronchodilating mediators are, e.g., PGE_1 and PGI_2 . All these mediators act via specific receptors on the bronchial smooth muscle. The chemical mediators capable of causing bronchoconstriction generally are released by precursors stored either in static cells fixed within tissue (the mast cells) or in mobile blood cells (the eosinophilic leukocytes) infiltrating the bronchial mucosa. The classic example of such a mediator release is the allergic challenge in allergic or extrinsic asthma, in which the allergen interacts with a specific immunoglobin E (IgE) antibody (antigen – antibody reaction, type I allergic reaction) fixed to the surface of mast cells. It is also possible that mediators are released by other nonallergic stimuli in nonallergic or intrinsic asthma.

The binding of the mediators histamine, leukotriene, PG, etc., or of β-adrenoceptor agonists to the corresponding receptors on the smooth muscle cells triggers intracellular changes in the concentrations of cAMP or cGMP. There is an optimal ratio of cAMP to cGMP. An increase in cAMP concentration or a fall in that of cGMP, triggered by β_2 -adrenergic sympathomimetics, PGE_1 , or phosphodiesterase inhibitors, such as theophylline, induces relaxation of smooth muscle. Conversely, a fall in cAMP concentration or a rise in that of cGMP triggered by vagal stimulation, cholinergic agonists, histamine, β-adrenergic antagonists, or $PGF_{2\alpha}$, causes contraction. Calcium plays an important role in the mast cell, where it interacts with cAMP in the regulation of granule release. The release of mediators (e.g., histamine and leukotrienes) is stimulated by a flow of calcium into the cell, possibly initiated by the IgE – antigen reaction at the cell surface.

Eosinophilic bronchial infiltration is one of the hallmarks of asthma. This infiltration is obviously caused by a dominant T lymphocyte helper cell subpopulation (so called T_{H2} cells → Blood, Chap. 2.1.3.), which, via secretion of various cytokines (i.e., IL-5), facilitates this eosinophilic inflammation. Eosinophils are thought to be the most important inflammatory cells in asthma.

Taking into consideration the pathophysiology of bronchial asthma, the therapy of this disease can be directed to several sites along the trigger-to-target organ response pathway. A causal therapy would include the prevention of exposure to precipitating factors, on the one hand, and the prevention of mast cell stimulation by hyposensitization or desensitization procedures (immunotherapy) on the other. Causal therapy is uncertain and difficult to accomplish. Current antiasthmatic therapy is therefore to a great extent symptomatic and its principal aim is to keep airway patency at the optimal level for each particular patient. The symptomatic therapy of asthma consists of bronchodilation by modification of the end-organ response, i.e., the smooth muscle response or by blockage of the cholinergic reflex pathways (vagal reflex) and of antiallergic therapy, including anti-inflammatory treatment, inhibition of antibody formation (immunosuppression), and prevention of mast cell degranulation or mediator antagonism. These symptomatic therapeutic measures are achieved by five main groups of substances: sympathomimetic agents, methylxanthines, anticholinergic drugs, corticosteroids, and disodium cromoglycate and related drugs. In the last few years new types of possible antiasthmatic agents have been proposed: leukotriene antagonists or inhibitors of leukotriene synthesis [6], [7].

2. Bronchodilators (Relievers)

This type of antiasthmatic drug acts on the bronchial smooth muscle and induces a relaxation of the airway muscle which leads to desired bronchodilation thus relieving the most prominent symptom of asthma. The term bronchodilator drug might be expected to cover any drug that causes dilation of the bronchi, but by common usage it is restricted to drugs with a fairly rapid action. Because this sort of therapy causes a more of less immediate relieve, therapy with bronchodilators is also known under the term reliever therapy.

2.1. Adrenoceptor Agonists

β-Receptor stimulation produces bronchodilation. This can be achieved by a wide variety of agents including those which release aminocatechols producing α and β effects (e.g., ephedrine), direct β stimulants which stimulate both β_1 and β_2 receptors (e.g. isoprenaline and adrenaline, which also has α effects), and drugs that are more selective in their stimulation of β_2 receptors (e.g., fenoterol, clenbuterol, and salbutamol) [8]. The development of relatively specific agents for β_2 stimulation left little place for ephedrine or other nonselective drugs that stimulate both β_1 and β_2 receptors and have adverse effects on the heart caused by β_1 stimulation (tachycardia, palpitations). The β_2-adrenoceptor agonistic bronchodilators can be used by inhalation, by oral, or by intravenous administration. In clinical practice the main problem in their use lies in the cardiovascular side effects and the skeletal muscle tremor caused by overdosage. Nevertheless, they are the drugs of choice in the treatment of acute bronchospasm. Long-acting β_2-adrenoceptor agonists have been introduced. They are especially useful in the treatment of nocturnal asthma attacks.

The parent compound of the sympathomimetic agents is 2-phenylethylamine. Substitutions on the benzene ring, on the α- and β-carbon atoms, or on the terminal amino group yield a wide range of compounds with sympathomimetic activity. They can be classified into aminocatechols, resorcinol derivatives, and saligenin derivatives depending on their chemical structure. Further substitutions on the benzene ring lead to other very active compounds, e.g., the long-acting clenbuterol, procaterol, or bitolterol.

Aminocatechols are largely eliminated by neuronal and extraneuronal uptake mechanisms at the sympathomimetic nerve terminals. Non-aminocatechols are resistant to both uptake mechanisms. The aminocatechols (adrenaline, isoprenaline, isoetharine, and rimiterol) containing a 3,4-benzenediol ring are also metabolized by the enzyme catechol-*O*-methyltransferase (COMT) to relatively inert 3-methoxy metabolites. Non-aminocatechols (resorcinol and saligenin derivatives) are not metabolized by this enzyme and thus their half-lifes are prolonged. Another widely distributed enzyme, monoamine oxidase (MAO), cleaves the aminocatechol between the α-carbon and the amino group. The removal of one or both of the hydroxyl groups from the benzene ring prevents the action of COMT, and substitution of the α-carbon atom and the amino group blocks oxidation by MAO.

2.1.1. Aminocatechol Derivatives

Epinephrine [*51-43-4*], adrenaline, 1-(3,4-dihydroxyphenyl)-2-(methylamino)ethanol, free base, $C_9H_{13}NO_3$, M_r 183.21, *mp* 211 – 212 °C (L-form); hydrochloride [*51-42-3*], $C_9H_{13}NO_3 \cdot HCl$, M_r 219.67, *mp* 147 – 154 °C (L-form); for pharmacology, see [9].

A naturally occurring hormone, L-epinephrine is produced by the medulla of the adrenal gland and released when the body is under stress (→ Hormones). It is the model for all other sympathomimetic drugs, but its clinical use has been largely supplanted.

Synthesis [10], [11]: see next page.

Trade names: Suprarenin (Hoechst, Germany), Medihaler Epi (Riker, United Kingdom, USA), Adrenalin (Parke-Davis, USA).

Isoproterenol [*149-53-1*], isoprenaline, 1-(3,4-dihydroxyphenyl)-2-(isopropylamino)ethanol, free base, $C_{11}H_{17}NO_3$, M_r 211.26, *mp* 155.5 °C (racemic form); hydrochloride [*949-36-0*], $C_{11}H_{17}NO_3 \cdot HCl$, M_r 247.72, *mp* 170 – 171 °C (racemic form); sulfate dihydrate [*6078-56-4*], $C_{11}H_{17}NO_3 \cdot 1/2\,H_2SO_4 \cdot 2\,H_2O$, M_r 296.33, *mp*128 °C (racemic form, some decomp.); for pharmacology, see [12].

Clinical use has been all but abandoned in Europe because isoproterenol is not selective for β_2 receptors.

Synthesis [13]: see right column, above.

Alternative synthesis [14]: see right column, centre.

Trade names: Aludrin (Boehringer Ingelheim, FRG), Aleudrin (Lewis, United Kingdom), Isomenyl (Kaken, Japan), Isuprel (Winthrop, USA).

Isoetharine [*530-08-5*], 1-(3,4-dihydroxyphenyl)-2-(isopropylamino)butanol, free base, $C_{13}H_{21}NO_3$, M_r 239.32, hydrochloride [*50-96-4*], $C_{13}H_{21}NO_3 \cdot HCl$, M_r 275.78, *mp* 212 – 213 °C (decomp.); for pharmacology, see [15].

The clinical use of isoetharine is declining because of its low β_2 specificity, but it is still used in combinations.

Synthesis [16]: see right column, below.

Trade names: Asthmalitan (Kettelhack-Riker, FRG), Numotac (Riker, United Kingdom), Bronkosol (Breon, USA).

Protokylol [*136-70-9*], 1-(3,4-dihydroxyphenyl)-2-(α-methyl-3,4-methylenedioxyphenethylamino)ethanol, free base, $C_{18}H_{21}NO_5$, M_r 331.37, *mp* 163 °C; hydrochloride [*136-69-6*], $C_{18}H_{21}NO_5 \cdot HCl$, M_r 367.83, *mp* 126 – 127 °C; for pharmacology, see [17]:

Synthesis [18]:

Trade names: Caytine (Chugai, Japan), Ventaire (Marion, USA).

Rimiterol [*32953-89-2*], 1-(3,4-dihydroxyphenyl)-1-(2-piperidinyl)methanol, free base, $C_{12}H_{17}NO_3$, M_r 223.27, *mp* 203 – 204 °C; hydrobromide [*31842-61-2*], $C_{12}H_{17}NO_3 \cdot HBr$, M_r 304.19, *mp* 220 °C (decomp.); for pharmacology, see [19].

Rimiterol is not in wide-spread clinical use.

Synthesis [20]:

Trade name: Pulmadil (Riker, United Kingdom).

Trimethoquinol [*30418-38-3*], tetroquinol, (−)-1-(3,4,5-trimethoxybenzyl)-1,2,3,4-tetrahydro-6,7-isoquinolinediol, free base, $C_{19}H_{21}NO_5$, M_r 343.38, *mp* 125 – 126 °C; hydrochloride [*18559-59-6*], $C_{19}H_{21}NO_5 \cdot HCl$, M_r 379.84; for pharmacology, see [21].

Trimethoquinol is a β-sympathomimetic agent that inhibits the aggregation of platelets.

Synthesis of D,L-trimethoquinol [22]:

The racemic mixture is resolved using (+)-tartaric acid to yield L-trimethoquinol.

Trade names: Inolin (Tanabe, Japan), Vems (ISF, Italy).

Hexoprenaline [*3215-70-1*], *N,N′*-bis[2-(3,4-dihydroxyphenyl)-2-hydroxyethyl]hexamethylenediamine, free base, $C_{22}H_{32}N_2O_6$, M_r 420.51, *mp* 162 – 165 °C; dihydrochloride [*4323-43-7*], $C_{22}H_{32}N_2O_6 \cdot 2\,HCl$, M_r 493.43, *mp* 197.5 – 198 °C; sulfate [*32266-10-7*], $C_{22}H_{32}N_2O_6 \cdot H_2SO_4$, M_r 518.59, *mp* 222 – 228 °C; for pharmacology, see [23].

Synthesis [24]: see next page.

Trade names: Etoscol (Byk Gulden, Germany), Etoscol (Morishita, Japan).

2.1.2. Resorcinol Derivatives

Metaproterenol [*586-06-1*], orciprenaline, 1-(3,5-dihydroxyphenyl)-2-(isopropylamino)-ethanol, free base, $C_{11}H_{17}NO_3$, M_r 211.26, *mp* 100 °C (racemic form); hydrochloride [*7104-40-7*], $C_{11}H_{17}NO_3 \cdot HCl$, M_r 247.72, *mp* 147 °C (racemic form); sulfate [*31023-56-0*], $C_{11}H_{17}NO_3 \cdot 1/2\,H_2SO_4$, M_r 260.30, *mp* 202 – 203 °C (racemic form); for pharmacology, see [25].

Metaproterenol was the first β-sympathomimetic drug with metabolic stability to achieve wide clinical use.

Synthesis [26]:

Alternative synthesis [27]:

Trade names: Alupent (Boehringer Ingelheim, Germany, France, United Kingdom, USA), Alotec (Boehringer-Tanabe, Japan).

Terbutaline [*23031-25-6*], 1-(3,5-dihydroxyphenyl)-2-(*tert*-butylamino)ethanol, free base, $C_{12}H_{19}NO_3$, M_r 225.29; sulfate [*23031-32-5*], $C_{12}H_{19}NO_3 \cdot 1/2\,H_2SO_4$, M_r 274.33, *mp* 246 – 248 °C; for pharmacology, see [28].

Terbutaline is a specific β_2-sympathomimetic agent in wide clinical use.

Synthesis [29]: see next page.

Trade names: Bricanyl (Astra, Germany, United Kingdom, USA), Bricanyl (Astra-Injisawa, Japan), Terbasmin (Erba, Italy).

Fenoterol [*13392-18-2*], 1-(3,5-dihydroxyphenyl)-2-(4-hydroxy-α-methylphenethylamino)ethanol, free base, $C_{17}H_{21}NO_4$, M_r 303.36; hydrobromide [*1944-12-3*], $C_{17}H_{21}NO_4 \cdot HBr$, M_r 384.28, *mp* 232 – 233 °C; for pharmacology, see [30].

Fenoterol is a selective β_2-sympathomimetic agent that is in wide clinical use in Europe.

Synthesis [31]:

Trade names: Berotec (Boehringer Ingelheim, Germany, Switzerland, Sweden, the Netherlands, Canada), Berotec (Warner-Lambert, United Kingdom, Ireland), Respilac (Angeli, Italy).

Reproterol [*54063-54-6*], 7-[-3-[[2-(3,5-dihydroxyphenyl)-2-hydroxyethyl]amino]propyl]-3,7-dihydro-1,3-dimethyl-1*H*-purine-2,6-dione, free base, $C_{18}H_{23}N_5O_5$, M_r 389.41; hydrochloride [*13055-82-8*], $C_{18}H_{23}N_5O_5 \cdot HCl$, M_r 425.88, *mp* 249 – 250 °C; for pharmacology, see [32].

Reproterol is structurally a combination of a β-sympathomimetic compound and theophylline, but it shows only sympathomimetic activity.

Synthesis [33]:

Trade names: Bronchospasmin (Chemiewerke Homburg, Germany), Bronchospasmin (Farmades, Japan), Bronchodil (Keymer, United Kingdom).

2.1.3. Saligenin Derivatives

Salbutamol [*18559-94-9*], albuterol, 2-(*tert*-butylamino)-1-(4-hydroxy-3-hydroxymethylphenyl)ethanol, free base, $C_{13}H_{21}NO_3$, M_r 239.32, *mp* 151 °C; sulfate [*51022-70-9*], $C_{13}H_{21}NO_3 \cdot 1/2\,H_2SO_4$, M_r 288.36; for pharmacology, see [34].

Salbutamol is a specific β_2-stimulant in wide clinical use in Europe and Japan.

Synthesis [35]:

Alternative synthesis [36]:

Trade names: Sultanol (Glaxo, Germany, Japan), Ventolin (Glaxo, France; Allen & Hanburys, United Kingdom; Sankyo, Japan), Broncovaleas (Valeas, Italy).

Salmeterol [*89365-50-4*], (±)-4-hydroxy-α^1-[[[6-(4-phenylbutoxy)hexyl]amino]methyl]-1,3-benzenedimethanol, 1-hydroxy-2-naphthoic acid salt [*94749-08-3*], $C_{25}H_{37}NO_4C_{11}H_8O_3$, M_r 603.75, *mp* 137 – 138 °C, for pharmacology see [90], [91]. Salmeterol is a long-acting β_2-agonist for patients with chronic asthma, useful also in controlling persistent nocturnal asthma. Synthesis [92]:

Trade name: Serevent (Glaxo Wellcome).

Pirbuterol [*38677-81-5*], α^6-[(*tert*-butylamino)methyl]-3-hydroxy-2,6-pyridinedimethanol, dihydrochloride [*38029-10-6*], $C_{12}H_{20}N_2O_3 \cdot 2HCl$, M_r 312.2, *mp* 182 °C (decomp.), acetate [*65652-44-0*], for pharmacology see [93]. Pirbuterol is a β_2-agonist in the management of disorders with reversible airways obstruction. It is given by inhalation and orally. Synthesis [94]:

Trade names: Exirec, Spirolair, Noxair, Zeisin (3M Medical).

2.1.4. Further Arylalkylamines

Modern β_2-specific sympathomimetics with different substituents on the aromatic ring are described in this group along with ephedrine and thiadrine.

Ephedrine [*299-42-3*], 2-methylamino-1-phenylpropanol, free base, $C_{10}H_{15}NO$, M_r 165.24, *mp* 79 °C (racemic form); hydrochloride [*50-98-6*], $C_{10}H_{15}NO \cdot HCl$, M_r 201.70, *mp* 187 – 188 °C; sulfate [*134-72-5*], $C_{10}H_{15}NO \cdot 1/2\,H_2SO_4$, M_r 214.28, *mp* 247 °C; for pharmacology, see [37].

Ephedrine is a naturally occurring alkaloid drug (→ Alkaloids) derived from *Ephedra equistina* and *Ephedra vulgaris*. It can be prepared synthetically. It is used mainly in combination with other agents.

Synthesis of L-(−)-ephedrine [38]:

Trade names: Ephetonin (E. Merck, Germany), Ephedrin (Knoll, Germany), Spaneph (Smith Kline & French, United Kingdom), Ephedrine "Nagai" (Dainippon, Japan), Calcidrine (Abbott, USA).

Thiadrine [*14007-67-1*], 3,4-dimethyl-2-imino-5-phenylthiazolidine, free base, $C_{11}H_{14}N_2S$, M_r 206.31; thiocyanate, $C_{11}H_{14}N_2S \cdot HSCN$, M_r 265.40, *mp* 190 – 192 °C; for pharmacology, see [39].

Thiadrine is not in wide-spread clinical use as a bronchodilator.

Synthesis [40]:

Trade name: Priatan (Chem. Werke Minden, Germany).

Clenbuterol [*37148-27-9*], 1-(4-amino-3,5-dichlorophenyl)-2-(*tert*-butylamino)ethanol, free base, $C_{12}H_{18}Cl_2N_2O$, M_r 277.20, *mp* 109.1 °C; hydrochloride [*21898-19-1*], $C_{12}H_{18}Cl_2N_2O \cdot HCl$, M_r 313.66, *mp* 174.0 – 175.5 °C; for pharmacology, see [41].

Clenbuterol is a long-acting, potent, and specific β_2 stimulator that is used orally.

Synthesis [42]:

Alternative synthesis [43]:

Trade name: Spiropent (Dr. Karl Thomae, Germany).

Mabuterol [*56341-08-3*], 1-(4-amino-3-chloro-5-trifluoromethylphenyl)-2-(*tert*-butylamino)ethanol, hydrochloride [*54240-36-7*], $C_{13}H_{18}ClF_3N_2O \cdot HCl$, M_r 347.21 for pharmacology see [44]. Mabuterol is an orally active β_2-adrenergic agonist related to Clenbuterol. Synthesis [45]:

Trade name: Broncholin (Kaken Pharmaceutical).

Tulobuterol [*41570-61-0*], 2-(*tert*-butylamino)-1-(2-chlorophenyl)ethanol, free base, $C_{12}H_{18}ClNO$, M_r 227.74, *mp* 89 – 91 °C; hydrochloride [*56776-01-3*], $C_{12}H_{18}ClNO \cdot HCl$, M_r 264.20, *mp* 165 – 170 °C; for pharmacology, see [46].

Synthesis [47]:

Trade names: Berachin (Toyo Tanabe, Japan), Hokunalin (Hokuriku Senjaku, Japan).

Carbuterol [*34866-47-2*], 1-(5-[2-(*tert*-butylamino)-1-hydroxyethyl]-2-hydroxyphenyl)urea, free base, $C_{13}H_{21}N_3O_3$, M_r 267.33, *mp* 205 – 207 °C; hydrochloride [*34866-46-1*], $C_{13}H_{21}N_3O_3 \cdot HCl$, M_r 303.79, *mp* 209 – 210 °C; for pharmacology, see [48].

Synthesis [49]:

Trade names: Bronsecur (Smith Kline & French, Belgium, the Netherlands, South Africa), Pirem (Gödecke/ Sasse, FRG).

Formoterol [*73573-87-2*], (*RR,SS*)-(±)-*N*-[2-hydroxy-5-[1-hydroxy-2-[[2-(4-methoxyphenyl)-1-methylethyl]amino]ethyl]phenyl]-formamide, semifumarate [*43229-80-7*], $C_{21}H_{26}N_2O_6$, M_r 402.21, for pharmacology see [50], [51]. Formoterol is a potent bronchoselective β-agonist with long duration of action given by inhalation.

Synthesis [52]:

Trade names: Foradil (Novartis Pharma), Atock (Rhône Poulenc), Oxis (Astra/pharma stern.)

Procaterol [*72332-33-3*], 8-hydroxy-5-[1-hydroxy-2-(isopropylamino)butyl]-2(1*H*)-quinolinone, $C_{16}H_{22}N_2O_3$, M_r 290.37, *mp* 141 – 142 °C; hydrochloride [*62929-91-3*], $C_{16}H_{22}N_2O_3 \cdot HCl \cdot 1/2\,H_2O$, M_r 335.83, *mp* 193 – 197 °C (decomp.); for pharmacology, see [53].

Synthesis [54]: see left column of next page, above.

Trade name: Meptin (Otsuka, Japan).

Bitolterol [*30392-40-6*], 4-[2-(*tert*-butylamino)-1-hydroxyethyl]-1,2-phenylene-bis(*p*-toluate), free base, $C_{28}H_{31}NO_5$, M_r 461.56, *mp* 80 – 84 °C; mesylate [*30392-41-7*], $C_{28}H_{31}NO_5 \cdot CH_4O_3S$, M_r 557.67, *mp* 170 – 172 °C; for pharmacology, see [55].

Synthesis [56]: see left column of next page, below.

Trade names: Effectin (Shionogi, Japan), Tornalate (Sterling Drug, USA).

Bambuterol [*81732-65-2*], (±)5-[2-(*tert*-butylamino)-1-hydroxyethyl]-*m*-phenylene-bis-(dimethylcarbamate), $C_{18}H_{29}N_3O_5$, M_r 367.45, hydrochloride [*81732-46-9*], $C_{18}H_{29}N_3O_5 \cdot HCl$, M_r 403.9, for pharmacology see [57], [58]. Bambuterol is an inactive prodrug of terbutaline (see page 6). It has a prolonged duration of action when administered orally.

Synthesis [59]:

Trade name: Bambec (Astra/pharma stern, Germany).

2.2. Xanthine Derivatives

This group includes the familiar compounds present in the stimulant beverages, i.e., caffeine (coffee, tea, cola), theobromine (cocoa), and theophylline (tea) [60–62]. All are methylated derivatives of the natural metabolite xanthine, a

precursor of uric acid. Apart from their stimulating effects, methylxanthines possess a number of properties that are clinically useful (diuretic effect, increase in cardiac output, vasodilation). Most xanthines have bronchodilator activity, but only some are employed therapeutically for this purpose.

The following processes contribute to the mechanism of action of theophylline. Phosphodiesterase inhibition enhances monophosphate (cAMP). The intracellular metabolism and concentration of calcium in bronchial smooth muscle (bronchodilation) and in the mast cells (inhibition of mediator release) change consecutively. Adenosine receptor antagonism also may contribute to the relaxation of bronchial smooth muscle and to the inhibition of histamine release from mast cells; adenosine is known to increase this release. Theophylline also influences prostaglandin synthesis.

Theophylline preparations can be administered intravenously, orally, or rectally. They would be ineffective and irritating if administered as aerosols. The major pharmacological problem with these agents is the enormous individual variability in their rates of absorption and metabolism. The unpredictability of its levels in plasma after oral administration and the low therapeutic index of theophylline make it difficult to handle, and careful monitoring of plasma levels may be required. Theophylline must be used in different preparations because its solubility in water is poor (about 1 %). Therefore, theophylline itself is not suitable for intravenous use, but is sufficiently soluble for oral administration. Theophylline is prepared as a soluble salt of ethylenediamine or of choline (choline theophyllinate) for intravenous use. True theophylline derivatives are 7-substituted compounds, e.g., dihydroxypropyltheophylline (proxyphylline). These are less potent bronchodilators than theophylline, but they cause less intestinal irritation than theophylline or its salts and are much used in Europe.

Theophylline [*58-55-9*], 3,7-dihydro-1,3-dimethyl-1*H*-purine-2,6-dione, $C_7H_8N_4O_2$, M_r 180.17, *mp* 270 – 274 °C.

Synthesis [63], [64]: see next column, above.

Trade names: Solosin (Cassella-Riedel, Germany), Neulin (Riker, United Kingdom), Phyllin

(Rona, United Kingdom), Theophyllol (Sankyo, Japan), Broncodyl (Breon, USA), Blixophyllin (Berlex, USA).

Theophylline ethylenediamine [*317-34-0*] is a salt of theophylline with ethylenediamine.

Trade names: Aminophylline (Promonta, Germany), Aminophylline (ICN; Searle; Wyeth; USA), Euphyllin (Byk Gulden, Germany), Cardophylin (Fisons, United Kingdom), Neophyllin (Eisai, Japan).

Etofylline [*519-37-9*], 3,7-dihydro-7-(2-hydroxyethyl)-1,3-dimethyl-1*H*-purine-2,6-dione, $C_9H_{12}N_4O_3$, M_r 224.22, *mp* 158 °C; for pharmacology, see [65].

Synthesis [66], [67]: see next page.

Trade names: Cordalin (Chemiewerke Homburg, Germany), Oxyphylline (Amido, France), Oxyphylline (Sankyo, Japan), Mesotin (Malescil, Italy).

Proxyphylline [*603-00-9*], 3,7-dihydro-7-(2-hydroxypropyl)-1,3-dimethyl-1*H*-purine-2,6-dione, $C_{10}H_{14}N_4O_3$, M_r 238.25, *mp* 135 – 136 °C; for pharmacology, see [68].

Synthesis [69]:

Trade names: Spantin (Pharmacia, Germany), Spasmolysin (Kade, Germany), Brontyl (Reckitt & Colman, United Kingdom), Monophylline (Yoshitomi, Japan).

Diprophylline [*479-18-5*], dyphylline, 7-(2,3-dihydroxypropyl)-3,7-dihydro-1,3-dimethyl-1*H*-purine-2,6-dione, $C_{10}H_{14}N_4O_4$, M_r 254.25, *mp* 158 °C.

Synthesis [67], [70]:

Trade names: Asthmolysin (Kade, Germany), Neutraphylline (Houdé, France), Neutraphylline (Cox-Continental, United Kingdom), Dihydrophylline (Tokyo Hosei, Japan), Neothylline (Lemmon, USA).

Acephylline piperazine [*18833-13-1*], acepifylline, piperazine salt of 1,2,3,6-tetrahydro-1,3-dimethyl-2,6-dioxo-7-purineacetic acid, $C_9H_{10}N_4O_4C_2H_5N$, M_r 281.27.

Synthesis [71]: The compound is synthesized by reacting theophylline with chloroacetic acid.

Trade name: Etaphydel (Delalande, Germany).

Bamifylline [*2016-63-9*], 3,7-dihydro-7-[*N*-ethyl-2-(hydroxyethylamino)ethyl]-8-benzyl-1,3-dimethyl-1*H*-purine-2,6-dione, free base, $C_{20}H_{27}N_5O_3$, M_r 385.47, *mp* 80 – 85.5 °C; hydrochloride [*20684-06-4*], $C_{20}H_{27}N_5O_3 \cdot HCl$, M_r 421.93, *mp* 185 – 186 °C; for pharmacology, see [72].

Synthesis [73]:

Trade name: Trentadil (Sedaph, France), Trentadil (Armour, United Kingdom).

2.3. Anticholinergic Drugs

The rationale for using anticholinergic drugs in the treatment of asthma is based on an irritant – bronchoconstrictor vagal reflex [74]. The allergen combines with antibodies on the surface of the mast cells releasing mediators that act on nervous receptors in the epithelium and elicit a reflex bronchoconstriction via the vagus nerves (parasympathetic nerves). Compounds, such as atropine (→ Alkaloids), which block transmission at parasympathetic neuroeffector junctions, inhibit vagally induced smooth muscle contraction and secretory activity. The clinical use of atropine has been discouraged because of fears of side effects (an increase in the sputum viscosity and a possible decrease in the ciliary activity). However, the clinical use of this type of compound has been reassessed in response to the introduction of ipratropium bromide [75] and oxitropium bromide. These drugs are inhaled. A long acting anticholinergic drug is tiotropiumbromide, which is in an advanced phase of development.

Atropine [*51-55-8*], D,L-hyoscyamine, 1αH,5αH-tropan-3α-ol (±)-tropate, *endo*-(±)-α-(hydroxymethyl)phenylacetic acid 8-methyl-8-azabicyclo[3.2.1]oct-3-yl ester, free base, $C_{17}H_{23}NO_3$, M_r 289.38, *mp* 114 – 116 °C; sulfate [*55-48-1*], $C_{17}H_{23}NO_3 \cdot 1/2\,H_2SO_4$, M_r 338.42, *mp* 190 – 194 °C; methylnitrate [*52-88-0*], $C_{17}H_{23}NO_3 \cdot CH_3NO_3$, M_r 366.42, *mp* 163 °C; for pharmacology, see [9].

Atropine is an alkaloid drug (→ Alkaloids) found in the plants *Atropa belladona, Datura stramonium*, and *Hyoscyamus niger.* L-Hyoscyamine is obtained by extraction from these plants and then transformed into the racemic form using an alkaline ethanol solution [76].

Trade names: Bronchovycrin (Endopharm, Germany), Perasthman Inhalat (Bissantz, Germany).

Ipratropium bromide [*22254-24-6*], (8*r*)-3α-hydroxy-8-isopropyl-1αH,5αH-tropanium bromide (±)-tropate, $C_{20}H_{30}BrNO_3$, M_r 412.38, *mp* 230 – 232 °C; for pharmacology, see [75], [77].

Synthesis [78]:

Trade name: Atrovent (Boehringer Ingelheim, Austria, Belgium, Germany, United Kingdom, Italy, Mexico, the Netherlands, Spain).

Oxitropium bromide [*30286-75-0*], 7(*S*)-(1α,2β,4β,5α,7β)-9-ethyl-7-(3-hydroxy-1-oxo-2phenylpropoxy)-9-methyl-3-oxa-9-azoniatricyclo[3.3.1.0^{2,4}]nonane bromide, $C_{19}H_{26}BrNO_4$, M_r 412.33, *mp* about 198 °C.

Synthesis [79]:

Trade name: Ventilat (Dieckmann, Germany), Tersigat (Laboratoires Francais de Thérapeutique, France).

Tiotropium bromide [*136310-93-5*] [7(*S*)-(1α,2β,4β,5α,7β]-7-[2-hydroxy-2,2-di(2-thienyl)acetoxy]-9,9-dimethyl-3-oxa-9-azoniatricyclo[3.3.1.0^{2,4}]nonane bromide, $C_{19}H_{22}BrNO_4S_2$, M_r 472.41, *mp* 226 – 227 °C (decomp.), bromide hydrate [*139404-48-1*], for pharmacology, see [80]

Synthesis [81]:

3. Antiinflammatory Drugs or Controllers (Glucocorticosteroids)

Glucocorticosteroids are the most potent agents available for the treatment of asthma [82]. When given orally, these substances cause adrenal suppression, metabolic side effects like obesity, osteoporosis, hyperglycemia, glycosuria, and disturbance of growth. However, when administered topically via inhalation glucocorticoid therapy can avoid these systemic side effect to a great extent. Therefore glucocorticoids given by inhalation have become the primary treatment of asthma. The mechanism of action of this type of compound is not fully understood, but it includes interaction with an intracellular glucocorticoid receptor [83]. The glucocorticoid receptor binds the steroid at its *C*-terminal part. After nuclear translocation the middle part of the receptor, which forms so-called "zinc fingers", interacts with DNA. An *N*-terminal domain then induces transcriptional transactivation of genes. In its inactivated form the glucocorticoid receptor is bound to a protein complex that includes heat shock proteins, immunophilline proteins, and others. The binding site of the DNA is termed glucocorticoid response elements (GRE). The interaction of the steroid receptor complex with GREs change the rate of transcription of steroid responsive genes resulting in either induction or repression of genes. Thereby production of inflammatory cytokines, enzymes, antiinflammatory proteins, receptors and adhesion molecules may be influenced. So for example β_2-receptors are upregulated which improves the efficacy of β-receptor agonists. This is known as the permissive effect of glucocorticoids.

Oral corticosteroid therapy suffers from a major drawback. The high dosage of steroids used to control inflammatory and immunologic reactions leads inevitably to unwanted, disturbing influences on metabolism; moreover withdrawal symptoms occur after long-term administration. Every effort should be made to avoid such long-term oral use. However, in severe case this cannot always be avoided. For intravenous administration during severe acute asthma (attacks), hydrocortisone (→ Hormones) is the preparation of choice, among other drugs. For oral corticosteroid therapy, prednisolone is preferred. For topical or inhalative treatment, aerosol preparations of beclomethasone dipropionate, betamethasone valerate, flunisolide, budenoside, and triamcinolone acetonide (→ Hormones) are available. In some countries fluticasone has already been introduced. Inhalative administration minimizes the metabolic side effects of the glucocorticoids. Side effects, like candidiasis of the mouth and hoarseness of the throat are usually mild and can be tolerated.

Beclomethasone [*4419-39-0*], 9α-chloro-11β,17α,21-trihydroxy-16β-methylpregna-1,4-diene-3,20-dione; 17,21-dipropionate [*5534-09-8*], $C_{28}H_{27}ClO_7$, M_r 510.97, *mp* 117 – 120 °C. Beclomethasone dipropionate is claimed to exert a topical effect on the lungs without significant systemic activity. It is used by inhalation, generally from a metered aerosol, for the prophylaxis of the symptoms of asthma [84], [85]. Chemical structure:

Trade names: Sanasthmax, Sanasthmyl (Glaxo, UK).

Flunisolide [*3385-03-3*], 6α-fluoro-11β,21-dihydroxy-16α,17α-isopropyldioxypregna-1,4-diene-3,20-dione, $C_{24}H_{31}FO_6$, M_r 434.5, hemihydrate [*77326-96-6*]. Flunisolide hemihydrate is administered by inhalation from metered aerosol and used in the management of asthma. Chemical structure:

Trade name: Inhacort (Boehringer Ingelheim, Germany).

Budesonide [*51333-22-3*], an epimeric mixture of α- and β-propylforms of 16α,17α-butylidendioxy-11β-21dihydroxy-pregna-1,4-diene, $C_{25}H_{34}O_6$, M_r 430.54. Comparative investigations of the clinical efficacy/safety of budesonide and beclomethasone dipropionate administered by inhalation in patients with chronic bronchial asthma showed no differences [86], [87]. Nebulized budenoside was effective in severe childhood asthma [88]. Chemical structure:

Trade name: Pulmicort (Astra/Pharma stern, Germany).

Fluticasone propionate [*80474-14-2*], *S*-fluoromethyl-6α,9α-difluoro-11β-hydroxy-16α-methyl-17α-propionyloxy-3-oxoandrosta-1,4-diene-17β-carbothioate, $C_{25}H_{31}F_3O_5S$, M_r 500.58, *mp* 272 – 273 °C (decomp.). Fluticasone propionate is claimed to exert a topical effect on the lungs without significant systemic effects, due to its low systemic bioavailability [89]. Chemical structure:

Trade name: Flutide (Glaxo Wellcome).

4. Antiallergic Therapy

Antiallergic therapy, including the use of corticosteroids, is an alternative to bronchodilator therapy in the treatment of asthma. The objectives of antiallergic therapy are the inhibition of mediator release, e.g., by disodium cromoglycate or related compounds (→ Antiallergic Agents, Chap. 3.) or by corticosteroids (→ Hormones, Chap. 4.), and the antagonism of mediators, e.g., by antihistamines or by the inhibition of either the activity or the synthesis of leukotrienes. The classical antihistamines are irrelevant to asthma therapy, presumably because of the presence and importance of other strong mediators. Newer antihistaminic agents, such as ketotifen [*34580-13-7*], have been employed in the treatment of asthma (→ Antiallergic Agents, Chap. 2.1.7.). Antagonists of cysteinyl-leukotrienes (i.e., leukotriene D_4 antagonists, zafirlukast, montelukast) or inhibitors of the enzyme 5-lipoxygenase are close to registration or already on the market (zileuton).

Disodium cromoglycate [*15826-37-6*] disodium 4,4'-dioxo-5,5'-(2-hydroxytrimethylenedioxy)di-14*H*-chromene-2-carboxylate, $C_{23}H_{14}Na_2O_{11}$, M_r 512.3, free acid [*16110-51-3*] is a relatively nontoxic agent used for the long-term prevention of many types of asthma [95]. It has no bronchodilator properties and is used in the prophylaxis of asthma.

It does not play a role in the treatment of acute asthmatic attacks including severe asthma [96], [97]. Chemical structure:

Disodium cromoglycate was developed from khellin, a natural substance that has been used for centuries to alleviate colic pains. It is a highly soluble powder that must be inhaled directly into the lung to be effective. Less than 1 % is absorbed when it is administered orally.

Trade name: Intal (Fisons).

Nedocromil sodium [*69049-74-7*], disodium 9-ethyl-6,9-dihydro-4,6-dioxo-10-propyl-4*H*-pyrano[3,2-*g*]quinoline-2,8-dicarboxylate, $C_{19}H_{15}Na_2O_7$, M_r 415.3; free acid [*69049-73-6*]. Nedocromil sodium has similar properties to sodium cromoglycate and can inhibit asthmatic responses provoked by allergen challenge and attenuate allergen-induced bronchial hyperresponsivness. It is rapidly absorbed from the lungs following inhalation and poorly absorbed from the gastrointestinal tract [98]. Chemical structure:

Trade name: Tilade (Fisons).

5. Antileukotrienes

It has been shown that leukotrienes (→ Prostaglandins, Chap. 2.) play a fundamental role in asthma. Especially the cystenyl leukotrienes are thought to be involved in the pathophysiology of asthma. The leukotriene antagonists montelukast and zafirlukast are the most prominent antileukotrienes which are registered or close to registration. Another possibility is to inhibit the synthesis of leukotrienes. The key enzyme is 5-lipoxygenase which, when inhibited, blocks the formation of leukotriene C_4, D_4, E_4 and of leukotriene B_4. Zileuton is the most advanced 5-lipoxygenase inhibitor, which has been introduced into the therapy of asthma in some countries.

Zafirlukast [*107753-78-6*], *N*-[4-[5-cyclopentyloxycarbonylamino)-1-methylindol-3-ylmethyl]-3-methoxybenzoyl]-2-methylbenzenesulfonamide, $C_{31}H_{33}N_3O_6S$, M_r 575.68. Chemical structure:

Zafirlukast is a potent LTC_4-, LTD_4- and LTD_4-antagonist and is clinically effective in patients with mild to moderate asthma [99], [100].

Trade name: Accolate (Zeneca).

Montelukast sodium [*151767-02-1*], sodium 2-[1-[1(*R*)-[3-[2(*E*)-(7-chloroquinolin-2-yl)vinyl]-phenyl]-3-[2-(1-hydroxy-1-methylethyl)phenyl]propylsulfanylmethyl]cyclopropyl]acetate, $C_{35}H_{35}ClNNaO_3S$, M_r 608.17, free acid [*158966-92-8*]. Chemical structure:

Montelukast sodium is a potent, selective competitive antagonist for cysteinyl leukotriene receptors such as LTD_4. It is orally active and shows therapeutic effects in patients with asthma [101].

Trade name: Singulair (Merck Frosst).

Zileuton [*111406-87-2*], (±)-*N*-(1-benzo[*b*]thien-2-ylethyl)-*N*-hydroxyurea, $C_{11}H_{12}N_2O_2S$, M_r 236.29. Chemical structure:

Zileuton is a potent and selective orally active 5-lipoxygenase inhibitor. It inhibited LTB_4 synthesis and was active in some inflammation models. Clinically it shows effects after acute and chronic administration in mild to moderate asthma [102], [103].

Trade name: Zyflo (Abbott).

6. Newer Concepts in Asthma Therapy

Various new and old approaches have been tried in the therapy of asthma. Calcium antagonists have no place in the routine management of asthma [7]. A substantial portion of ongoing research concentrates on phosphodiesterase inhibitors of type IV. The isoenzyme phosphodiesterase is located in inflammatory cells like the eosinophils which are important in asthma. There are also trials going on using humanized monoclonal antibodies against IgE, IL-5, IL-4, tumor necrosis factor α (TNFα) or adhesion molecules. Search for inhibitors of inducible NO synthetase is also continuing. Efforts are made to influence various transcription factors (i.e., NF_KB) or to find inhibitors of phospholipase A2 and antagonists for neurokinin receptors. Endothelin receptor antagonists are in development. Also potassium channel openers are still under evaluation. Time will show which of those various approaches will lead to novel therapies of asthma.

1. Introduction

1.1. General Definition

In 1942, WAKSMAN defined antibiotics as chemical substances produced by microorganisms and capable of inhibiting the growth of microorganisms [20]. Great effort has been devoted to the worldwide search for new antibiotics, and numerous compounds possessing various biological activities, that is, antibacterial, antiviral, antifungal, antitumor, and enzyme-inhibiting activities, have been discovered. These substances are mostly of microbial origin but are also semisynthetic in some cases. They have a wide variety of structural characteristics. Each is entered in the index of antibiotics. The area defined by the term "antibiotics" is therefore expanding, although WAKSMAN's original definition is still basically valid.

1.2. Historical Development and Classification

In 1877, PASTEUR observed that saprophytic bacteria inhibited the growth of pathogenic anthrax organisms. His was the first scientific description of the antagonism phenomenon. Production of a certain metabolic substance seemed to be responsible for the inhibition. PASTEUR suggested the therapeutic potential of this type of growth repression. VUILLEMIN used the term "antibiosis" to describe the inhibition of the growth of one organism by another. The potential utility of "bacteriotherapy" was recognized and enormous experimental efforts were made to investigate the antagonism phenomenon.

In 1894, METCHNIKOFF reported the repressive effect of *Pseudomonas* on *Vibrio cholerae.* From the culture of a *Penicillium,* GOSIO isolated an antibacterial crystalline substance, mycophenolic acid, in 1896. Other results also demonstrated the ability of various microbes to produce antibacterial substances [21].

It was in 1929 that FLEMING observed that a culture of a *Penicillium* inhibited the growth of bacteria [22]. He demonstrated the production of an antibacterial substance in the culture broth and named it penicillin. Although he suggested the promising therapeutic utility of penicillin, none of the attempts to isolate penicillin were successful and immediate attention was not attracted for the next decade. Instead, synthetic chemotherapeutics, such as sulfonamides, became objects of general interest after the discovery of prontosil by DOMAGK in 1935 [23]. The antibiotics, many of which were known even before the discovery of penicillin, remained without great importance for decades. Only the outbreak of the Second World War in 1939 led to an intense worldwide search for drugs to treat infections and wounds. Toward the end of the 1930s, FLOREY, CHAIN, and co-workers began to investigate penicillin in the course of their systematic study of antibacterial substances. They demonstrated the marked activity and therapeutic value of penicillin in 1940 and the "antibiotic era" began [24]. The production of penicillin had until that time been unsatisfactory, and favorable conditions for the effective formation of the antibiotic were explored in the United States. An active culture of the penicillin-producing organism was sought and submerged fermentation was developed. The use of lactose as a carbon source and the addition of cornsteep liquor to the nutrients were found effective. Irradiation of the culture with X-rays or ultraviolet light produced mutant strains. These findings set the stage for the industrial production of penicillin.

After the discovery of penicillin, BROTZU began a search for antibiotic-producing organisms and examined a culture of *Cephalosporium* spp. isolated from the sea near a sewage outlet in Sardinia. It secreted substances active against gram-positive bacteria. In September of 1948, BROTZU sent his organism to ABRAHAM at Oxford for detailed inspection. Several antibiotics were isolated from the culture and named cephalosporin [25]. Particular attention was at-

tracted by cephalosporin C, crystallized from the crude mixture of antibiotics, because of its low toxicity and its resistance to penicillinase.

Penicillins and cephalosporins, both of which possess a β-lactam ring as a structural characteristic, are designated β-lactam antibiotics. Extensive attempts to improve their antibacterial spectra through chemical modifications led to the development of many kinds of semisynthetic penicillins and cephalosporins. Moreover, nontraditional β-lactams have been discovered and commercialized [26–29].

Other novel antibiotics were discovered among the products of fungi, bacteria, and actinomycetes [30]. As a result of a search for water-soluble and heat-stable substances which would be active against gram-negative bacteria, WAKSMAN isolated actinomycin in 1940, streptothricin in 1942, and streptomycin in 1944 from cultures of actinomycetes. Various other antibiotics were isolated from microbes in France, Germany, Japan, the United Kingdom, the United States, and other countries.

Actinomycin is a peptide antibiotic effective against tumor cells as well as bacteria. Peptide antibiotics, one of the major antibiotics groups, possess diverse activities, i.e., antibacterial, antifungal, and antitumor activities. Their structures are varied and feature complicated modes of connection of often unusual amino acids. Ring peptides, linear peptides, lactonic peptides, and peptides containing hydroxy acids have been isolated. The group includes actinomycins, gramicidins, polymyxins, and colistins.

Streptomycin is used for infections of gram-positive and gram-negative bacteria and as a specific medicine for tuberculosis. Kanamycin, discovered by UMEZAWA in 1957, is especially effective against resistant bacteria. Paromomycin, spectinomycin, and ribostamycin were isolated later. These antibiotics are called aminoglycosides because their structural units are amino sugars, sugars, and amino acids. They are water soluble and basic in nature. The mechanism of resistance to aminoglycosides has been closely investigated and derivatives for use active against the resistant bacteria have been developed.

A yellow substance showing antibacterial activity was found in 1948 among products of *Streptomyces aureofaciens* and was named aureomycin. Terramycin was isolated from the fermentation broth of *Streptomyces rimosus.* The chemical and structural similarities of the two soon became apparent; they each have a linearly fused tetracyclic structure of six-membered rings. This parent skeleton is designated "tetracycline," and aureomycin and terramycin are now called chlortetracycline and oxytetracycline, respectively.

Chloramphenicol was first isolated as a product of *Streptomyces venezuelae;* it showed a broad antimicrobial spectrum. Chloramphenicol is an unusual natural product because it possesses both chloro and nitro groups in its structure. It is the only antibiotic produced commercially by an entirely chemical synthesis.

Macrolides are macrocyclic lactones to which sugars are attached. Various clinically important antibiotics are macrolides. Erythromycin, isolated in 1952, has two sugars connected to different sites on the 14-membered ring aglycone. Dimethylamino sugars are often found in macrolide antibiotics. Macrolides are classified as 12-, 14-, or 16-membered ring macrolides.

Polyene antibiotics have a conjugated olefinic structure in the macrocyclic lactone moiety, as is the case with amphotericin B, and sometimes lack the amino sugar moiety. Polyenes are produced mainly by *Streptomyces* and show antifungal activity. Ansamycin has an aliphatic "ansa" bridge spanning two nonadjacent positions of the aromatic system. Rifamycin is a representative ansamycin possessing a 1,4-naphthoquinone moiety. Benzenoid ansamycins having a hydroquinone moiety are also known.

In 1950, rhodomycin was isolated from the culture broth of *Streptomyces purpurascens* by BROCKMANN and his co-workers. Structural analysis disclosed that rhodomycin is a glycoside, combining an amino sugar and a 7,8,9,10-tetrahydro-5,12-naphthacenequinone moiety. Structurally similar antibiotics have since been discovered, and the generic name "anthracycline" has been assigned. The aglycone of anthracycline is called anthracyclinone. Daunorubicin and doxorubicin are representative anthracycline antitumor antibiotics. Aclacinomycin, recently isolated by UMEZAWA, possesses three sugars and is of interest because of its low toxicity.

The first nucleoside antibiotic, cordycepin, was isolated in 1950. Various nucleoside an-

tibiotics of unusual structure have subsequently been isolated and are important as antibacterials, antineoplastics, and agricultural chemicals.

In addition to the antibiotics previously described, various unclassified antibiotics have been isolated. Their structures are not always fully known, although they exhibit significant biological activity. The most important antibiotics and derivatives are discussed in this article. Some representative compounds that have recently been introduced in clinics are also described. These include the new semisynthetic penicillins and the cephalosporins. Clearly the field of antibiotics is experiencing dynamic growth.

1.3. Nomenclature

In principle, it is the privilege of the discoverer to name to his or her new antibiotic. Usually antibiotics are named after the producing organisms or some aspect of their chemical and biological nature. In accordance with the suggestions of the Nomenclature Committee of the American Society of Microbiology [31], names of antibiotics should be based on (a) the family to which the antibiotic belongs, (b) the chemical structure of the compound, or (c) some property of the antibiotic. If, for some reason, a name cannot be given to the new antibiotic, a code designation may be given.

2. Chemotherapeutic Use of Antibiotics

2.1. Microbial Pathogens

Microorganisms that can be treated by chemotherapy include bacteria, fungi (→ Antimycotics), viruses, rickettsia, and protozoa (→ Chemotherapeutics).

Outside the cytoplasmic membrane, bacteria have a rigid shell called the cell wall that is not seen in mammalian cells. The main constituent of the cell wall is peptidoglycan, a cross-linked structure of long parallel chains of polysaccharides and short peptide chains. Bacteria are separated into two classes based on the results of a Gram's stain. Gram-positive bacteria hold the color of the primary stain and gram-negative ones are decolorized and are stained by the counterstain. The structure and constituents of the cell walls of gram-positive and gram-negative bacteria are slightly, but distinctly, different.

Some antibiotics are effective only against gram-positive bacteria whereas others are active against gram-negative ones. Streptomycin and kanamycin are effective against mycobacteria as well as gram-positive and gram-negative bacteria. Chloramphenicol and tetracyclines are broad-spectrum antibiotics active against not only the usual bacteria but also rickettsia.

2.2. Tumor Cells

Certain antibiotics are effective for clinical treatment of cancer. Cancer cells function abnormally, escaping growth regulation. Antibiotics occupy an important position among the various agents for cancer chemotherapy. At present, doxorubicin, daunorubicin, mitomycin C, bleomycin, actinomycin D, chromomycin A_3, and neocarzinostatin are used clinically. They interact with DNA to inhibit polymerases of DNA and RNA, or to cause DNA strand breakage. Normal cells are also damaged to some extent; the selective toxicity is generally based on the unusually rapid multiplication of the tumor cells. Some of these antibiotics also possess antineoplastic activity because they inhibit the synthesis of DNA.

2.3. Enzyme Inhibitors

The action of antibiotics can be interpreted as a direct or indirect inhibition of certain enzyme systems. The activity of an antibiotic can be recognized only when its site of action is critically important to the maintenance of the life of the cell. However, various enzyme inhibitors of microbial origin have been found useful as medicines even though they do not exhibit antibiotic activity [32]. For example, pepstatin, an inhibitor of pepsin isolated by Umezawa in 1970 from *Streptomyces testaceus,* shows promise for the treatment of gastric ulcer, but its therapeutic effects are not based on any antibiotic action.

2.4. Chemotherapeutic Uses

Chemical and bacteriological diagnoses are especially important for successful chemotherapy because the choice of drug depends primarily on the sensitivity of the microorganism to the drug. The antimicrobial activity of an antibiotic is expressed as the minimum inhibitory concentration (MIC) measured by the dilution method. Antibiotics are administered by hypodermic, intramuscular, or intravenous injections, or as internal medicines. For external applications, they are given according to the nature of the antibiotic and the characteristics of the disease. Doses large enough to maintain a sufficient drug concentration in the blood and tissues are prescribed. Various undesirable side effects of antibiotics have been reported. One of the serious side effects is the allergic reaction to penicillins. Oto- and nephrotoxicity result from the long-term use of aminoglycosides in quantity. Aplastic anemia caused by chloramphenicol also has been reported. Antitumor and antiviral antibiotics are generally highly toxic.

2.5. Use in Agriculture

Although antibiotics were originally developed for use against microbial diseases in humans, they are also applicable to agriculture. Several antibiotics are used in the treatment of animal and plant diseases. Kasugamycin and blastcidin S are effective against rice blast disease. Polyoxins are selectively effective against certain species of phytopathogenic fungi. Penicillins, tetracyclines, mikamycins, erythromycins, tylosins, spiramycins, and thiopeptins are used in animal feeds to stimulate growth. The mechanism of growth enhancement induced by these antibacterial antibiotics is unknown. The use of antibiotics as an additive in animal fodder has led to considerable improvement in agricultural production. Antibiotics, on the one hand, prevent breeding diseases, afflictions, and mortality in young animals. On the other hand, antibiotics, even in very small quantities (on the order of 5 – 20 mg per kilogram of fodder mixture), enhance the growth and full utilization of fodder in, e.g., pigs and poultry. For all antibiotics that are used simultaneously as therapeutic agents and fodder additives, there is the danger of developing a resistance. Therefore, worldwide efforts are directed at avoiding the use of the therapeutically important antibiotics, particularly the penicillins and the tetracyclines, as feed additives. Instead, these antibiotics are used only for genuine veterinary treatment in compliance with certain controls and quarantine guarantees.

2.6. Resistance

An organism becomes resistant to an antibiotic if it survives continued contact. Antibiotics repress the growth of the sensitive organism in a culture, resulting in the survival of naturally resistant organisms. Microbial resistance can be acquired through a spontaneous or induced mutation. Various examples of cross-resistance have been observed and several cross-resistant groups of antibiotics are recognized. Combined use of two antibiotics retards the appearance of resistant organisms.

2.7. Units

The production, isolation, and processing of commercial products require careful control for all pharmaceuticals. Because of the extremely high sensitivity and the danger of diminished activity, this consideration has always been particularly important.

The Oxford unit (O. U.) is defined as the amount of penicillin that just prevents the growth of a certain *Staphylococcus aureus* species. Very pure crystalline penicillin salts generally have constant biological activities and the Oxford unit has been replaced by the international unit: 1 mg of pure benzylpenicillin sodium contains 1670 O. U.; the O. U. specific to this salt was declared to be the international unit (I. U., usually abbreviated U). Conversely, 0.6 μg of benzylpenicillin sodium has the activity of 1 I. U. Because the biological activity comes from the penicillin nucleus, the change to another cation leads to a change in activity proportional to the molecular mass. This change can be calculated. The activities of the chief penicillin salts are:

benzylpenicillin sodium	1670 U/mg
benzylpenicillin potassium	1598 U/mg
benzylpenicillin procaine	1011 U/mg
penicillin-2-hydroxyprocaine	1008 U/mg
penicillin-*N,N′*-dibenzyl-ethylenediamine	1213 U/mg
penicillin-*N*-ethylpiperidine	1328 U/mg.

The mass of 1 U, for benzylpenicillin sodium, 0.6 µg, is extremely small. The following larger units of mass are used in production and trade:

1 Mega U	$= 1 \times 10^6$ I. U.
	= 600 mg benzylpenicillin sodium
	= ca. 1 g benzylpenicillin procaine
1 Mio Mega U	$= 1 \times 10^{12}$ I. U.
	= 600 kg benzylpenicillin sodium
	= ca. 1 t benzylpenicillin procaine

The activities of some older penicillins are given in I. U.

phenoxymethylpenicillin:	1 mg free acid	1699 U
phenethicillin:	1 mg D-potassium salt	1476 U
	1 mg L-potassium salt	1470 U
penicillin O:	1 mg potassium salt	1612 U

All other penicillins that are used therapeutically can be made very pure and the preparations are dosed and traded in mass units (µg, mg, g, kg).

2.8. Analysis

The practical determination of active substances in penicillins and other antibiotics can be divided among three types of methods [25]:

1) Microbiological testing (see Chap. 7).
2) Determination of the contents by chemical or enzymatic conversion followed by a physical method, such as colorimetry.
3) Purely physical methods, such as UV or IR absorption.

3. Classification of Antibiotics

3.1. β-Lactams

The β-lactam group includes natural penicillins, semisynthetic penicillins, natural cephalosporins, semisyntheric cephalosporins, cephamycins, 1-oxacephems, clavulanic acids, penems, carbapenems, nocardicins, and monobactams.

3.1.1. Natural Penicillins

Penicillin was discovered in 1929 by Fleming [22]. At first it was obtained as a mixture of several similar compounds, but these were later separated from each other. The β-lactam structure of penicillin was proposed by Abraham and Chain and supported by Woodward, but it was opposed by those who believed in the alternative thiazolidine-oxazole structure [33]. The β-lactam structure was finally established by an X-ray crystallographic analysis performed by Hodgkin and Low [34]. Penicillins G, F, K, X, and N, dihydropenicillin F, and isopenicillin N have been isolated from the fermentation broths of *Penicillium notatum* or *P. chrysogenum*. These compounds differ only in the R moiety of structure **1**.

1

Name	R
Penicillin G (Benzylpenicillin) [61-33-6]	Penicillin F [118-53-6]	$CH_3CH_2CH{=}CHCH_2-$
Dihydropenicillin F [4493-18-9]	$CH_3(CH_2)_4-$
Penicillin K [525-97-3]	$CH_3(CH_2)_6-$
Penicillin X [525-91-7]	Penicillin N [525-94-0]	Isopenicillin [58678-43-6]	
Of these, penicillin G shows good stability, activity, and rate of production by microorganisms. Total synthesis of penicillin V was achieved by Sheehan and Henery-Logan in 1957 [35]. Biogenic syntheses of penicillin – cephalosporin antibiotics also have been reported [36], [37].

3.1.2. Semisynthetic Penicillins

Several limitations have become apparent concerning the antibiotic activity of benzylpenicillin. This drug is not very active against gram-negative bacteria; it is inactivated by penicillinase produced by resistant organisms, and it is not suitable for oral administration because it breaks down under acidic conditions. Penicillins having different side chains have been made by adding appropriate precursors to the fermentation [33]. Various penicillins have been obtained biosynthetically. Among these is phenoxy-methylpenicillin, the first used by oral administration. In contrast, 6-aminopenicillanic acid (6-APA, **2**, R is NH_2) can be prepared by either enzymatic or chemical means. Penicillin amidase or penicillin acylase cleaves the side chain of penicillin to produce 6-APA. The amide bond of the side chain is also efficiently cleaved by treatment with phosphorus pentachloride [25, p. 27]. Penicillins with modified side chains (**2**) have been synthesized from 6-APA via the acyl chloride method, the ethyl or isobutyl chloroformate method, or the dicyclohexylcarbodiimide method in order to improve the antibacterial spectra and increase the stability against penicillinase [33, p. 59]. Ampicillin is active against gram-negative bacteria, and carbenicillin and sulbenicillin are effective against *Pseudomonas.* Ampicillin and amoxicillin are suitable for oral administration. Methicillin, oxacillin, cloxacillin, dicloxacillin, flucloxacillin, and naficillin are resistant to β-lactamase. Mecillinam has an unusual amidino side chain and is relatively stable and effective against gram-negative bacteria.

Modification of the carboxyl group has been found to be effective for the purpose of oral administration, and penicillin esters (**3**) have been developed [33, p. 59]. These are absorbed and hydrolyzed by the small intestine to release free acids of the parent penicillins.

2

Name	R
Penicillin V (Phenoxymethylpenicillin) [87-08-1]	$C_6H_5OCH_2CONH-$ (biosynthetic)
Penicillin O [87-09-2]	$CH_2{=}CHCH_2SCH_2CONH-$
Phenethicillin [147-55-7]	$C_6H_5OC(CH_3)HCONH-$
Propicillin [551-27-9]	$C_6H_5OC(C_2H_5)HCONH-$
Phenbenicillin [1926-48-3]	$C_6H_5OC(C_6H_5)HCONH-$
Carbenicillin [4697-36-3]	$C_6H_5-C(H)(COOH)-CONH-$
Sulbenicillin [41744-40-5]	$C_6H_5-C(H)(SO_3H)-CONH-$
Ticarcillin [34787-01-4]	Methicillin [61-32-5]	Nafcillin [147-52-4]	Oxacillin [66-79-5]	Cloxacillin [61-72-3]	
Dicloxacillin [3116-76-5]

Flucloxacillin [5250-39-5]

Ampicillin [69-53-4]

Apalcillin [63469-19-2]

Mezlocillin [51481-65-3]

Piperacillin [61477-96-1]

Amoxicillin [26787-78-0]

Cyclacillin [3485-14-1]

Hetacillin [3511-16-8]

Mecillinam [32887-01-7]

3.1.3. Natural Cephalosporins

The fermentation broth of *Cephalosporium* spp. isolated by BROTZU contained several antibiotics: cephalosporin P, penicillin N, and cephalosporin C. Cephalosporin P was shown to be an acidic steroidal substance. Cephalosporin C was active against gram-negative bacteria, resistant to β-lactamase, and much less toxic than penicillin. The chemical structure of cephalosporin C was determined by ABRAHAM and NEWTON [25]. It consists of 7-aminocephalosporanic acid (7-ACA) and D-α-aminoadipic acid (see **4**). Treatment of cephalosporin C with acetyl esterase yields deacetylcephalosporin C, which exhibits about 20 % of the antibacterial activity of cephalosporin C. The allylic acetoxy group of cephalosporin C can be hydrogenated in the presence of palladium – charcoal catalyst to yield deacetoxycephalosporin C, which shows 10 % of the activity of the parent cephalosporin C [25]. WOODWARD and his co-workers synthesized cephalosporin C in a fully stereospecific manner [38].

3

Name	R^1	R^2
Talampicillin [47747-56-8]		Pivampicillin [33817-20-8]		Bacampicillin [50972-17-3]		
Pivmecillinam [32886-97-8]		
3.1.4. Semisynthetic Cephalosporins

Because the antibacterial activity of cephalosporin C itself is relatively low, the development of a more active derivative is desirable. The phosphorus pentachloride method has been applied to the cephalosporin system to produce 7-aminocephalosporanic acid (7-ACA) in high yield [25, p. 27]. The 3′-acetoxy group of cephalosporin is easily replaced by various nucleophiles [25, p. 134]. Modification

of the 7-amino group and the 3′ group make possible the various cephalosporin derivatives **4a** [33, p. 59]. Cephaloridine, cefazolin, and cefamandole are active against gram-negative bacteria. Cefuroxime, cefotaxime, and ceftizoxime have a methoxyimino group and a 2-aminothiazole ring in common and are resistant to β-lactamase. Cefoperazone is particularly active against *Pseudomonas*. All of these are used by injection. On the other hand, several cephalosporins are used only by oral administration. These include cephalexin, cephaloglycin, cefradine, cefadroxil, cefaclor, cefroxadine, and cefatrizine.

4

Name	R
Cephalosporin C [61-24-5]	$OCOCH_3$
Deacetylcephalosporin C [1476-46-6]	OH
Deacetoxycephalosporin C [26924-74-3]	H

Cephalosporins are also obtainable via the ring expansion reaction of penicillin sulfoxide first devised by MORIN [25, p. 183]. Thus, cephalexin is produced by chemical conversion of phenoxymethylpenicillin or benzylpenicillin.

3.1.5. Cephamycins

Substances similar to cephalosporin C were found among the products of various streptomycetes and were characterized by the presence of a 7α-methoxy group. They are named cephamycins after their cephem skeleton (see **5**) and their production by streptomycetes [39], [29, vol. 1, p. 199]. They are strongly resistant to β-lactamase and effective against gram-negative bacteria and bacteria that have acquired resistance to penicillins and cephalosporins. Semisynthetic cephamycins (**5a**) with improved activities are obtained by chemical transformations.

Cefsulodin [62587-73-9]		
Cephaloridine [50-59-9]		Cefatrizine [51627-14-6]		

Cefoxitin, synthesized from cephamycin C, is particularly active against various gram-negative bacteria and stable to β-lactamase. Cefmetazole, produced from 7-ACA, has almost the same antibacterial spectrum as cefoxitin and maintains its high concentration in blood. Cefotetan is reported to be more active than cefoxitin against gram-negative bacteria (for structures see page 53).

Chemical modification of cephamycins requires special devices for the following reasons. 7-Aminocephamycinoic acid (7-ACMA; **6**), which corresponds to the 7-ACA of cephalosporins, is not easily isolated because of its instability.

It has methoxy and amino groups on the same carbon atom of the β-lactam ring and the elimination of the protonated amino group is quite facile, because of the electron-donating nature of the methoxy group. Moreover, the usual phosphorus pentachloride method cannot be applied to the side chain cleavage of cephamycin C because a strong N – P bond is formed by the reaction of the carbamate moiety of cephamycin C with phosphorus pentachloride [40]. Instead, exchange of the α-aminoadipoyl side chain for another acyl group is achieved by treating the fully protected cephamycin C with the appropriate acyl chloride in the presence of a neutral acid scavenger. This is followed by the simultaneous removal of the amino protective group and the α-aminoadipoyl group [41]. The side chain transformation is also effected using an acyl chloride and partially hydrated molecular sieves [42].

Chemical conversion of cephamycin into 7-ACMA ester has been reported [43].

3.1.6. 1-Oxacephems

In addition to the modification of the side chains of natural β-lactam antibiotics, totally or partially synthetic nuclear analogs of penicillins

and cephalosporins have been explored extensively [28], [33, p. 59]. In 1974 WOLFE reported the first 1-oxacephem (**7**) derived from penicillin, but its antibacterial activity remains unknown because the amino and carboxy protective groups have not been removed. Racemic 1-oxacephalothin (**8**), synthesized by CHRISTENSEN and his co-workers in the same year, was found to be antibacterially active, suggesting that the sulfur atom is not always necessary for the expression of antibiotic activity. Racemic 1-oxacefamandole is twice as active as cefamandole and the activity of optically active 1-oxacephalothin (**8**) is four to eight times as high as that of cephalothin. NAGATA and his co-workers discovered latamoxef (**9**) (moxalactam, 6059-S), which exhibits strong activity against pathogenic anaerobes, such as *Bacteroides fragilis,* as well as gram-negative bacteria, including *Pseudomonas* [29, vol. 2, p. 1]. It is completely stable against various β-lactamases and has low toxicity. A high plasma-peak level and long duration are maintained. Latamoxef is a nuclear analog of cephamycin that has a 2-(4-hydroxyphenyl)malonylamino side chain and a 1-methyltetrazolylthio moiety; it is produced on an industrial scale by a totally chemical process starting with *epi*-penicillin *S*-oxide [44], [45].

3.1.7. Clavulanic Acids

In the course of screening the substances inhibiting β-lactamase, which is responsible for bacterial resistance to penicillins and cephalosporins, a potent β-lactamase inhibitor, clavulanic acid, was isolated from *Streptomyces clavuligerus* [46]. The antibiotic activity of clavulanic acid is not strong, but it has a broad antibacterial spectrum. Instead, it is effective synergistically when used with β-lactamase-sensitive penicillins and cephalosporins against β-lactamase-producing organisms. Clavulanic acid is characterized by its 1-oxadethiapenam ring system and lack of the side chain at position 6. Several congeners of clavulanic acid have been isolated [27], [29, vol. 2, p. 361], [47]. Clavam-2-carboxylic acid, 2-hydroxymethylclavam, and 2-formyloxymethylclavam exhibit antifungal activity [48].

Name	Structure
Methyl (6*S*,7*S*)-3-methyl-8-oxo-7-phthalimido-5-oxa-1-azabicyclo[4.2.0]-oct-2-ene-2-carboxylate [*54997-17-0*]	 **7**
1-Oxacephalothin [*54214-83-4*]	 **8**
Latamoxef (Moxalactam, 6059-S) [*64952-97-2*]	 **9**

3.1.8. Penems

The penem ring system has not been found in nature; it has been designed artificially by WOODWARD [26, p. 167], [28], [29, vol. 2, p. 315]. That the antibacterial activity of β-lactam antibiotics is based on their ability to acylate enzymes is widely accepted. In penicillins, the rigid, nonplanar bicyclic system enhances the reactivity of the β-lactam ring by diminishing the delocalization of the unshared electron pair of the amide nitrogen onto the adjacent carbonyl group. On the other hand, in cephalosporins, where the β-lactam nitrogen is bonded almost planar, the double bond of the six-membered ring interacts with the unshared electrons of the β-lactam nitrogen, diminishing the delocalization to the amide carbonyl. Therefore, the β-lactam ring of cephalosporins is cleaved easily. Penems combine the two structural elements, the five-membered ring and the double bond. 6-Acylaminopenem-3-carboxylic acids (**10**), 6-

unsubstituted penem-3-carboxylic acids (**11**), and 6-alkylpenem-3-carboxylic acids (**12**) have been synthesized. The β-lactam moiety with two asymmetric centers derives from penicillin, and the five-membered ring fused with it is formed by the intramolecular Wittig reaction [29, vol. 2, p. 315]. Various 2-substituents, such as H, CH_3, C_2H_5, $CH_2C_6H_5$, and $SCH_2CH_2NHCOCH_3$, have been introduced. Although the activity of compound **10** with $R = CH_3$ was disappointing, presumably because of its low stability, 6-unsubstituted penems (**11**) exhibit powerful antibiotic activity [49]. 6-Monoalkylpenems (**12**) show interesting activity in general. The penems having bulky substituents at C-6 are biologically inactive because of the low reactivity of their β-lactam rings.

Name	Structure
Clavulanic acid [*58001-44-8*]	ß-Hydroxypropionyl clavulanic acid [*64675-12-3*]	Clavam-2-carboxylic acid [*71657-61-9*]	2-Hydroxymethyl-clavam [*66036-39-3*]	2-Formyloxymethyl-clavam [*66036-40-6*]	
3.1.9. Carbapenems

Cabapenems are a family of antibiotics having the 1-azabicyclo[3.2.0]hept-2-ene system [27], [29, vol. 2, p. 227]. The first carbapenem antibiotic, thienamycin, was discovered at Merck in 1976 among the fermentation products of *Streptomyces cattleya* [50]. Antibiotics of this type have been isolated one after another in the search for inhibitors of bacterial cell wall synthesis and β-lactamase. From the fermentation broth of *Streptomyces olivaceus,* the Beecham group isolated olivanic acids MM4550, MM13902, MM17880, MM22380, MM22381, MM22382, and MM22383 [51–54]. Epithienamycin A, B, C, D, E, and F were found by the Merck group [55–58]. Some of olivanic acids and epithienamycins are identical. Olivanic acid MM4550 is identical to MC696-SY2-A found by UMEZAWA as a product of *Streptomyces fulvoviridis* [59]. The antibiotics designated PS-5, −6, and −7 were isolated by Sanraku-Ocean in collaboration with Panlabs from *Streptomyces cremeus,* subsp. *auratilis* A271 [60–63]. Carpetimycin A and B, reported by the Kowa Company, are products of *Streptomyces* spp. [64], [65]. Asparenomycin A was isolated by the Shionogi research group from *Streptomyces tokunonensis* and *Streptomyces argenteolus* [66].

Name	Structure
6-Acylaminopenem-3-carboxylic acid	 **10**
Penem-3-carboxylic acid	 **11**
6-Alkylpenem-3-carboxylic acid	 **12**

Carbapenems are classified into three classes according to the mode of substitution on the β-lactam ring, that is, *trans*-carbapenems (thienamycin, epithienamycins C and D, PS-5, F-6, and F-7), *cis*-carbapenems (epithienamycin A, B, E, and F, MC696-SY2-A, carpetimycin A and B), and ene-carbapenems (asparenomycin A, B, and C). The 5*R* configuration seems significant for biological activity. The instability of the carbapenems and low broth titer cause difficulties in the determination of the structure.

Asparenomycin
[76466-24-5]

Thienamycin is active against a wide range of gram-positive and gram-negative bacteria, including the ones resistant to conventional β-lactam antibiotics. Carpetimycins and asparenomycin are also effective against resistant bacteria.

Chemical modifications and a great deal of synthetic study of carbapenems have been un-

dertaken to improve the stability of the carbapenem skeleton and compensate for the low productivity of the microbes. This is one of the most important fields of antibiotics [67–80], [69, p. 1142].

Naturally occurring carbapenems have several functional groups that have been subjected to chemical modifications to improve their stability and antibacterial potency [54]. The aminoethylthio side chain plays an important role in extending the antibiotic activity, especially the antipseudomonal activity, and is also thought to be a cause of the instability of carbapenems, presumably by intramolecular aminolysis of the β-lactam ring. Derivatives of the aminoethylthio group, carboxyl group, and hydroxyethyl side chain are being sought.

Name	R
Nocardicin A [39391-39-4]	Nocardicin B [60134-71-6]	Nocardicin C [59511-12-5]	Nocardicin D [61425-17-0]	Nocardicin E [63555-59-9]	Nocardicin F [63598-46-9]	Nocardicin G [65309-11-7]	
3.1.10. Nocardicins

A mutant strain of *Escherichia coli* showing specific supersensitivity to β-lactam antibiotics has been developed at the Fujisawa Research Laboratories and used to isolate nocardicins from *Nocardia uniformis* by a screening procedure [81]. The nocardicin structure has been elucidated by spectroscopic analysis and chemical degradation. The noncardicins are monocyclic β-lactam antibiotics [27], [29, vol. 2, p. 165], [47, p. 281]. Several congeners differing in the side chains have been isolated. Among them, significant activity is exhibited only by nocardicin A, which is active against gram-negative bacteria, especially *Pseudomonas aeruginosa, Proteus,* and *Neisseria,* but inactive against gram-positive bacteria.

3.1.11. Monobactams

Sulfazecin was isolated in 1981 by the Takeda group as a product of *Pseudomonas acidophila* by screening using organisms highly sensitive to β-lactams [82]. The structure was shown to be a monocyclic β-lactam. **Isosulfazecin**, a diastereomer of sulfazecin, also was isolated by the same group. In the same year, the Squibb group reported on a group of monocyclic β-lactams produced by *Agrobacterium, Chromobacterium,* and *Gluconobacter* [83]. A compound (SQ 26 445) identical to sulfazecin was included. Sykes proposed the name "monobactam" for compounds characterized by the 3-acylamino-2-oxoazetidine-1-sulfonic acid group. In monobactams, the β-lactam ring presumably is activated by the electronic effect of the sulfonate moiety alone, in contrast to the case of penicillins and cephalosporins. Because the antibacterial activity of sulfazecin is not satisfactory, many derivatives have been synthesized chemically [29, vol. 3, p. 339]. Among them **aztreonam** (SQ 26 776), synthesized from threonine, has been found highly effective [84].

Sulfazecin [77912-79-9]

Isosulfazecin [77900-75-5]

Aztreonam [78110-38-0]

3.2. Tetracyclines

The discovery of the tetracyclines, the first being aureomycin (7-chlorotetracycline), was one of the great successes of the worldwide screenings, i.e., testing of media samples and other materials, for the presence of antibiotic-producing microorganisms.

The first patents and publications of Lederle Laboratories [85], marked the beginning of an extensive stream of publications and patents that reflect the medical, industrial, and economic importance of the tetracyclines [86], [87].

3.2.1. Structure and Properties

The linear four-ring-system skeleton is characteristic of the tetracyclines (**13**) and has given the whole group its name. The strongly conjugated system of keto and enol groups is of particular significance for the biological activity. The structures of the first tetracyclines were elucidated and proved by synthetic work, e.g., that of MUXFELDT et al., shortly after their discovery and parallel to their clinical testing and industrial development. The chief tetracyclines are listed under structure **13** (see next page).

The tetracyclines are bright yellow compounds, amphoteric, and with the exception of rolitetracycline and similarly constructed derivates insoluble in water at the isoelectric point. Their salts, e.g., hydrochlorides, are soluble in water and can be administered either parenterally or orally, although the low pH of the solution causes some problems in the latter instance.

3.2.2. Anhydrotetracyclines

Tetracyclines are aromatized in ring C by dehydration with concentrated acids, e.g., aqueous hydrochloric acid or anhydrous hydrogen chloride in acetone, to form anhydrotetracyclines (**14**, wherein $R^1 - R^5$ are similar to those of **13**) [88–90]. These compounds have less biological activity than the starting compounds. Their formation, like that of the *epi*-anhydrotetracyclines, must be avoided because they are toxic to the kidneys. An interesting fact is that antibiotics with the anhydrotetracycline structure also are formed in nature and can be isolated from cultures of microorganisms, e.g., chelocardin from *Nocardia sulfurea* [91].

14

3.2.3. Anthracyclines

Structurally these antibiotics belong to the tetracyclines. They are characterized by the *p*-quinone structure of ring C in addition to the aromatic nuclei B and D (see **15**). Here $R^1 - R^5$ are simple substituents, such as H, OH, or CH_3. Only R^6 is a sugar or similarly complex group. Although anthracyclines show antibacterial activity, they have not been used as antibiotics because of their relatively high toxicity and strong side effects. The antitumor activity of rhodomycin was discovered by ARCAMONE et al. in 1961 [92], and various antitumor anthracyclines were subsequently isolated [93]. The most important anthracyclines are listed under structure **15**. Daunorubicin and doxorubicin are representative anthracyclines. Aclarubicin was found by UMEZAWA during a search for anthracyclines that might have lower cardiac toxicity

than doxorubicin. Anthracyclines exert their effect by interacting with DNA, the primary cellular receptor [94].

3.3. Aminoglycosides

WAKSMAN initiated the screening of antibiotics and, after finding actinomycin and streptothricin, he discovered the first useful aminoglycoside, streptomycin, in 1944 [95–99]. After wide use of penicillin, streptomycin, chloramphenicol, and tetracycline, resistant organisms appeared in hospital patients. In 1957, staphylococci and gram-negative organisms resistant to all the known antibiotic drugs caused serious infections; kanamycin was discovered at that time by UMEZAWA and was introduced clinically. However, in 1965, kanamycin-resistant strains appeared. In 1967, the enzymatic mechanism of resistance to aminoglycoside antibiotics was elucidated. UMEZAWA suggested that 3′-phosphotransferase and 6′-acetyltransferase, which transferred the terminal phosphate of ATP to the 3′-hydroxyl group of kanamycin, neomycin, and paromomycin or the acetyl group of acetyl-CoA to the 6′-amino group, were involved in the mechanism of resistance [100], [101]. In order to prove this enzymatic mechanism of resistance conclusively, 3′-deoxykanamycin A and 3′,4′-dideoxykanamycin B were synthesized and used to demonstrate the inhibition of the growth of resistant strains [102]. This conclusively demonstrated the enzymatic mechanism of resistance. Effective derivatives were obtained not only by deoxygenation but also by modification of the 1-amino group, which was involved in binding to the enzymes.

More than 150 naturally occurring aminoglycosides have been isolated from culture filtrates of *Streptomyces, Streptoverticillium, Nocardia, Micromonospora, Streptoalloteichus, Dactylosporangium, Saccharopolyspora,* and other bacterial strains.

D

Naturally occurring aminoglycoside antibiotics

1) **Noncyclitol aminoglycosides**
   a) *Monosaccharide derivatives*
   3-amino-3-deoxy-D-glucose, nojirimycin, *N*-carbamoyl-D-glucosamine, streptozotocin, prumycin
   b) *Disaccharides* (trehalosamines)
   trehalosamine, mannosyl glucosaminide, 4-amino-4-deoxytrehalose
   c) *Diaminosorbitol aminoglycosides* (sorbistins)
   sorbistins A_1, A_2, B, D
   d) *Glycocinnamoylspermidines*
   LL-BM123β, γ_1, γ_2, glysperins A, B, C
2) **Aminoglycosides containing neutral cyclitols and monoaminocyclitols**
   kasugamycin, myomycins A, B, C, LL-BM782α_1, α_{1a}, α_2, minosaminomycin, LL-BM123α, validamycins A, B, C, D, E, F
3) **Aminoglycosides containing streptamine and related aminocyclitols**
   a) *Streptidine aminoglycosides* (streptomycins)
   streptomycin, mannosidostreptomycin, dihydrostreptomycin, hydroxystreptomycin (reticulin), *N*-demethylstreptomycin, mannosidohydroxystreptomycin, glebomycin (bluensomycin)
   b) *Actinamine aminoglycosides* (spectinomycins)
   spectinomycin (actinospectacin), dihydrospectinomycin
   c) *4-Substituted deoxystreptamine aminoglycosides* (neamines)
   neamine, paromamine, nebramine (nebramycin 8), lividamine, NK-1003, seldomycin factor 2, gentamines C_1, $C_{1\alpha}$, C_2, apramycin (nebramycin 2), oxyapramycin (nebramycin 7)
   d) *5-Substituted deoxystreptamine aminoglycosides* (destomycins)
   hygromycin B, destomycins A, B, C, A-396−1, SS-56-C, A16316-C
   e) *4,5-Disubstituted deoxystreptamine aminoglycosides* (neomycins)
   neomycins B, C, LP-B, LP-C, paromomycins I, II, lividomycins A, B, mannosyl paromomycin, ribostamycin, xylostasin, ribosyl paromamine (LL-BM408α), butirosins A, B, BU-1709E_1, E_2, BU-1975C_1, C_2
   f) *4,6-Disubstituted deoxystreptamine aminoglycosides* (kanamycins)
   kanamycins A, B, C, NK-1001, NK-1012−1, NK-1013−1, NK-1013−2, tobramycin (nebramycin 6), 6″-*O*-carbamoylkanamycin B (nebramycin 4), 6″-*O*-carbamoyltobramycin (nebramycin 5′), 2′-*N*-carbamoyltobramycin (nebramycin 11), 3″-deamino-3″-hydroxytobramycin (nebramycin 12), 6′-*N*-carbamoyltobramycin (nebramycin 13), gentamicins A, A_1, A_2, A_3, A_4, B, B_1, C_1, C_{1a}, C_2, C_{2a}, C_{2b} (sagamicin), X_2, JI-20A, JI-20B, G-418, I-1, 6′-*C*-methylgentamicin A (II-2), 6′-*C*-methylgentamicin A (III-1), VII-1, VII-3, VII-5, seldomycin factors 1, 3, 5, sisomicin, verdamicin, G-52, 66−40B, 66−40C, 66−40D, 3″-*N*-demethylsisomicin (66−40G)
4) **Aminoglycosides containing 1,4-diaminocyclitols**
   a) *Fortamine aminoglycosides* (fortimicins)
   fortimicins A, C, D, KG_3, 3-*O*-demethylfortimicin A, sporaricin A, 2″-*N*-carbamoylsporaricin A, 2″-*N*-formylsporaricin A, istamycins A (sannamycin A), A_1, A_2, B, B_1, C, C_1, dactimicin (SF-2052), 2″-*N*-formylfortimicin A
   b) *Non-glycine fortamine aminoglycosides*
   fortimicins B, E (AE, KH), AH, AI, AK (KI), AL, AM, AO, AP, AQ, AS, KE, KF, KG, KG_1, KG_2, KO_1, KQ, sporaricin B (KA-6606 II), KA-6606 V, VI, sannamycins B (KA-7038 II, istamycin A_0), C(KA-7038 VI), KA-7038 III, IV, V, VII, istamycin B_0, C_0

Kanamycins are produced by *Streptomyces kanamyceticus,* gentamicins by *Micromonospora purpurea*, and butirosins by *Bacillus circulans.* Many compounds analogous to aminoglycoside antibiotics are produced by the same strain. For example, more than 20 compounds structurally analogous to gentamicin have been isolated from a culture filtrate of a *Micromonospora* strain [103], [104].

Most aminoglycoside antibiotics that are important for chemotherapy contain 1,3- or 1,4-diaminocyclitols named actinamine,

2-deoxystreptamine, fortamine, or streptidine. Among these naturally occurring aminoglycosides, dihydrostreptomycin, kanamycin A, kanamycin B, lividomycin A, ribostamycin, sisomicin, spectinomycin, streptomycin, tobramycin, a mixture of gentamicins C_1, C_2, and C_{1a}, a mixture of neomycins B and C, and a mixture of paromomycins I and II are commercially available as chemotherapeutic agents useful in treating infections. Hygromycin B and destomycin A are used as animal anthelmintics. Kasugamycin and validamycin A are used for the prevention of plant diseases. Among resistant bacteria of clinical origin, the most important mechanism of resistance to aminoglycoside antibiotics is the inactivation by *O*-phosphorylation, *O*-nucleotidylation, or *N*-acetylation of specific sites of the antibiotic. The gene for these enzymes is located on a plasmid. Organisms with resistance resulting from permeability barriers to drugs have been isolated, but ribosomal resistance to aminoglycosides is very rare in organisms isolated clinically. Studies of the enzymatic mechanism of resistance to aminoglycosides have been reviewed extensively [105–108].

Semisynthetic Aminoglycosides have been made. Based on the enzymatic mechanism of resistance, studies of the chemical synthesis of derivatives that inhibit the growth of resistant strains have been initiated. 3′-Deoxykanamycin A has been synthesized and used to inhibit the growth of resistant strains having aminoglycoside-3′-phosphotransferase enzymes. Dibekacin (3′,4′-dideoxykanamycin B), synthesized from kanamycin B, shows a strong activity not only against resistant staphylococci and gram-negative organisms but also against *Pseudomonas* [102]. These results prove the enzymatic mechanism of resistance.

Streptomycin, the first aminoglycoside antibiotic, was discovered by WAKSMAN. This drug is produced by *Streptomyces griseus* and extracted from the culture filtrate by adsorption on a column of Amberlite IRC-50 resin. The hydrogen chloride – calcium chloride ($3\,HCl \cdot 1/2\,CaCl_2$) complex salt of streptomycin is easily crystallized from an anhydrous methanol solution. Streptomycin is also produced by several other strains: *Streptomyces bikiniensis, Streptomyces olivaceus, Streptomyces poonensis, Streptomyces mashuensis, Streptomyces galbus, Streptomyces rameus,* and *Streptomyces erythrochromogenes* subsp. *narutoensis.*

The early structural studies have been reviewed [109]. The two anomeric configurations were found to be α-L by application of Hudson's rules of isorotation and NMR spectral analysis. The absolute structure of streptomycin has been confirmed by X-ray analysis of its oxime selenate [110]. Streptomycin has been synthesized by oxidation of dihydrostreptomycin [111].

Streptomycin
[*57-92-1*]
R = CHO

Dihydrostreptomycin
[*128-46-1*]
R = CH_2OH

Spectinomycin (Actinospectacin, M-141) is produced by *Streptomyces spectabilis* and *Streptomyces flavopersicus.* It is also produced by *Streptomyces hygroscopicus* subsp. *sagamiensis.* Spectinomycin hexahydrate is crystallized from an aqueous acetone solution. This antibiotic is labile, especially in acidic solution.

Spectinomycin (**16**)
[*1695-77-8*]

The structure of spectinomycin (**16**) was revealed by chemical studies, and its stereochemistry was determined by X-ray analysis of its dihydrobromide pentahydrate crystal [112]. To-

tal synthesis of spectinomycin has been accomplished [113], [114].

Neomycin (Fradiomycin), a mixture of **Neomycins B and C,** is produced by *Streptomyces fradiae* and by *Streptomyces albogriseolus*. It is marketed as a mixture that contains 85 – 90 % neomycin B [115]. Neomycins B and C are extremely stable in neutral or alkaline aqueous solution.

The final structure and stereochemistry of neomycins B and C were established in 1962. Neomycin C has also been synthesized also [116].

Paromomycin (Catenulin, Aminosidin, Hydroxymycin, Zygomycin A) is produced by *Streptomyces rimosus* subsp. *paromomycinus*; the structures of two isomers, paromomycins I and II, have been proposed. Paromomycin I is the main component of paromomycin preparations.

Catenulin, produced by *Streptomyces catenulae;* amminosidin, produced by *Streptomyces chrestomyceticus;* hydroxymycin, produced by *Streptomyces paucisporogenes;* and zygomycin A, produced by *Streptomyces pulveraceus,* are identical with paromomycin. Zygomycin A_1 is identical with paromomycin I and zygomycin A_2 is identical with paromomycin II.

The absolute configurations of the paromomycins have been determined along with those of other deoxystreptamine-containing aminoglycosides and dihydrostreptomycin [117], [118].

Ribostamycin (SF-733) is produced by *Streptomyces ribosidificus.* The free base is crystallized from methanol solution. The structure has been determined by chemical methods and total synthesis has been undertaken [119].

Kanamycin A is produced by *Streptomyces kanamyceticus.* The monosulfate monohydrate and the free base are crystallized from aqueous methanol. Kanamycin A is extremely stable in neutral or alkaline aqueous solutions.

The stereochemical structure of kanamycin A has been confirmed by X-ray analysis of its monosulfate monohydrate and monoselenate monohydrate crystals [120]. Total synthesis of kanamycin A has been achieved [121].

Kanamycin B (Bekanamycin, Aminodeoxykanamycin) is one of the two minor components that have been isolated from the culture filtrate of kanamycin-producing *Streptomyces kanamyceticus.* Kanamycin B has a retention factor (R_f) of 0.37, whereas kanamycin A, the major component, shows R_f 0.21 – 0.26. (R_f is a measure of the relative mobilities of substance and solvent in a chromatographic system.) The free base kanamycin B is crystallized from aqueous *N,N*-dimethylformamide.

Gentamicin (Gentamicin C Complex), a mixture of **Gentamicins C_1, C_{1a}, and C_2,** is the antibiotic complex produced by *Micromonospora purpurea* and *Micromonospora echinospora.* Gentamicins C_1 and C_2 are the principal products, and C_1 is itself a mixture of two major components designated C_1 and C_{1a}. Gentamicin C complex, which consists of the mixture of C_1 and C_{1a} (60 – 80 %) and of C_2 (20 – 40 %), has been used as a chemotherapeutic agent. The structures and the stereochemistry of the gentamicin C components have been reported [122].

Sisomicin (66 – 40, Rickamicin) is the major antibiotic produced by *Micromonospora inyoensis.* Its structure has been elucidated [123].

Dibekacin (3′,4′-Dideoxykanamycin B, DKB) was the first drug developed on the basis of the enzymatic mechanism of resistance to aminoglycosides. Dibekacin is synthesized from kanamycin B by the application of the Tipson-Cohen deoxygenation method after selective *N*- and *O*-protections [102]. A modified synthetic route via the 3′,4′-epoxy compound has given a high yield of more than 40 % on an industrial scale [124].

Amikacin (1-*N*-[(*S*-)-4-Amino-2-hydroxybutyryl]kanamycin, BB-K$_8$) is synthesized in 22 % yield from the 6′-*N*-protected kanamycin by selective 1-*N*-acylation with *N*-protected (*S*)-4-amino-2-hydroxybutyric acid using the active ester method [125]. The most important point of this synthesis is the selective protection of all of the amino groups except the 1-amino group. The 3,6′-di-*N*-protected kanamycin has been obtained in 95 % yield by selective *N*-protection using chelation with Co^{2+}, Ni^{2+}, and Cu^{2+} [126]. A new 3,6′,3″-tri-*N*-protection method using the selective 3″-*N*-trifluoroacetylation of the 3,6′-di-*N*-protected kanamycin with ethyl trifluoroacetate has been developed and the synthesis via 3,6′-di-*N*-(benzyloxycarbonyl)-3″-*N*-(trifluoroacetyl)kanamycin gives amikacin in a yield of more than 60 % [127].

The Fortimicin Group is a new type of deoxyaminoglycoside antibiotics, each consisting of glycine and a pseudodisaccharide, that have been found by screening. Fortimicin is produced by a *Micromonospora* species, sporaricin by *Saccharopolyspora hirsuta* subsp. *kobensis,* istamycin by *Streptomyces tenjimariensis,* sannamycin by *Streptomyces sannanensis,* and dactimicin by *Dactylosporangium matsuzakiense* [128–131], [128, p. 1061]. The structures of the fortimicin antibiotics are shown. These antibiotics strongly inhibit the growth of gram-positive and gram-negative bacteria but most *Pseudomonas* strains are resistant to them.

The axial amino group at C-1 in fortimicin A and istamycin A can be acetylated by aminoglycoside acetyltransferase(3)-I, but the equatorial amino group at C-1 in sporaricin A and istamycin B is scarcely acetylated. Other aminoglycoside-modifying enzymes that participate in the resistance to deoxystreptamine-containing aminoglycosides do not inactivate fortimicin-group antibiotics.

3-*O*-Demethyl derivatives of sporaricin A and istamycin B exhibit good activity not only against gram-positive and gram-negative bacteria but also against most *Pseudomonas* strains. These derivatives will be developed as valuable chemotherapeutic agents in the near future.

Fortimicin B
[54783-95-8]

3.4. Nucleosides

The biological effects associated with metabolic processes and specific enzyme control mechanisms are diverse in naturally occurring nucleosides and their synthetic analogs. Nucleosides exhibit several biological effects, including antibiotic, anticancer, and antiviral activities. They possess antimitotic and immunosuppressive activities and cardiovascular and other effects [132–134]. Moreover, it should be kept in mind that nucleoside analogs can assume other functional roles not as yet recognized, and that further therapeutic applications can be expected in the future. These analogs are obtained predominantly from microbial sources.

The nucleoside antibiotics consist of a heterocyclic base aglycone and a carbohydrate or a carbocyclic ring linked by a carbon – nitrogen (*N*-nucleoside) or a carbon – carbon bond (*C*-nucleoside). The nucleoside antibiotics fall somewhat outside the normal field of antibiotics with respect to their activity spectra and hence to their use. They are important for use against fungi, viruses, and certain types of cancer cells. Some typical nucleoside antibiotics are mentioned here.

3.4.1. *N*-Nucleosides

5-Azacytidine (**17**), a triazine analog of cytidine produced by *Streptoverticillium ladakanus*. It is active against some bacterial strains, Ehrlich ascitic tumor, leukemia L1210, and certain other leukemias. 5-Azacytidine also inhibits the DNA synthesis of bacteriophage T4 [135].

17
5-Azacytidine
[*320-67-2*]

Bredinin (**18**), produced by *Eupenicillium brefeldianum,* shows marked immunosuppressive activity in mice, interferes with replication of *Vaccinia* virus in vitro, and inhibits leukemia L 5178 cells and *Candida albicans* [136].

18
Bredinin
[*50924-49-7*]

Coformycin (**19a**) is isolated from *Nocardia interforma* along with formycin. Coformycin shows a synergistic effect with formycin on Yoshida rat sarcoma cells because of its strong inhibition of adenosine deaminase, which inactivates formycin. Coformycin, having a characteristic seven-membered ring base moiety, is thought to be a typical example of a "transition-state analog" in the adenosine deaminase reaction. 2′-Deoxycoformycin (**19b**) has also been isolated also [137–139].

19a: R = OH
Coformycin
[*11033-22-0*]

19b: R = H
2′-Deoxycoformycin
[*53910-25-1*]

Cordycepin (**20**), 3′-deoxyadenosine, was one of the first nucleoside antibiotics isolated from *Cordyceps militaris.* It inhibits *Bacillus subtilis, Mycobacterium tuberculosis,* KB cell cultures, and Ehrlich ascites tumor cells.

20
Cordycepin
[*73-03-0*]

Crotonoside (**21**), isolated from *Croton tiglium* seeds, acts as a vasopressor [140].

21
Crotonoside
[*1818-71-9*]

Nebularine (**22**), produced by the mushroom *Agaricus* (*Clitocybe*) *nebularis,* inhibits the growth of *Mycobacterium tuberculosis* and *Brucella abortus,* and is markedly cytotoxic to mammalian cells, whereas the purine base is relatively nontoxic. Nebularine is toxic to Sarcoma 180 cells [141], [142].

22
Nebularine
[*550-33-4*]

Toyocamycin (**23a**), produced by *Streptomyces toyocaensis,* strongly inhibits *Candida albicans, Trichophyton interdigitale,* and *Mycobacterium tuberculosis* and is also active against NF-sarcoma cells [143]. **Tubercidin** (**23b**) and **sangivamycin** (**23c**) also belong to this class [144].

23a: R = CN Toyocamycin [*606-58-6*]
23b: R = H Tubercidin [*69-33-0*]
23c: R = $CONH_2$ Sangivamycin [*18417-89-5*]

Polyoxins A – O (**24**, **25**, **26**) are peptide nucleosides produced by *Streptomyces cacaoi*. They possess various heterocycles, e.g., uracil, thymine, 5-hydroxymethyluracil, uracil-5-carboxylic acid, or formylimidazolone. The compounds **24** and **26** are particularly active against sheath-blight in rice, *Pellicularia sasakii,* and are widely used as agricultural drugs [145–147].

3.4.2. *C*-Nucleosides

Formycin (**27**) (**Formycin A**) is isolated from *Nocardia interforma* and from *Streptomyces lavendulae* [148], [149]. The antibiotic is effective against *Xanthomonas oryzae* and *Pellicularia filamentosa*. Its activity against Yoshida rat sarcoma cell is enhanced by coformycin. **Formycin B** (**28**) inhibits *Xanthomonas oryzae* and interferes with multipli-

cation of influenza A virus in the cells of chick chorioallantoic membrane [150]. **Oxoformycin B** (**29**) shows no activity against *Xanthomonas oryzae* [151].

3.4.3. Carbocyclic Nucleosides

Since the pioneering synthesis of the racemic carbocyclic analog of adenosine by SHEALY and CLAYTON and the subsequent isolation of **aristeromycin** (**32**) from *Streptomyces citricolor*, the interest in this class of compounds has been renewed by the isolation of a new carbocyclic nucleoside, **neplanocin A** (**33**). The latter exhibits remarkable antitumor activity against L 1210 leukemia in mice, and its synthetic analogs are now being studied extensively [154–156].

3.4.4. An Exceptional Nucleoside

Blasticidin S (**34**) has a pyran ring as the sugar moiety and inhibits various gram-positive and gram-negative bacteria. It is particularly effective against *Pericularia oryzae* and is now used as an agricultural drug [157].

34
Blasticidin S
[*2079-00-7*]

3.5. Macrolides

This group of antibiotics is characterized by excellent antibacterial activity, particularly against gram-positive bacteria. Macrolides can be defined and distinguished from the other groups of antibiotics by the unique feature of their chemical structure. They are polyfunctional macrocyclic lactones and the majority of them contain at least one amino sugar moiety, which is the cause of the basicity of the molecules. Neutral macrolides containing only a neutral sugar moiety are also known. These antibiotics have become targets in the aldol strategy of organic synthesis to construct their polyhydroxy functions stereoselectively [158], [159]. The antibiotics are classified as either 12-, 14-, or 16-membered ring macrolides according to the ring size of the aglycone.

3.5.1. 12-Membered Ring Macrolides

Methymycin (**35**), produced by *Streptomyces venezuelae,* was first shown to be a 12-membered lactone, comprising the aglycone or methynolide and D-desosamine [160], [161]. **Neomethymycin** (**36**) has an isomeric structure.

[*497-72-3*]
Neomethymycin (**36**) R^1 = H, R^2 = OH
[*497-73-4*]

3.5.2. 14-Membered Ring Macrolides

The erythromycins, produced by *Streptomyces erythreus,* are clinically important macrolides and are the most widely investigated 14-membered ring macrolides [162]. Extensive chemical and X-ray crystallographic studies of **erythromycin A** (**37**) have established its structure as well as those of its minor components, **erythromycin B** (**38**), **erythromycin C** (**39**), and **erythromycin D** (**40**). Erythromycin is effective against streptococcal and pneumococcal infections. Derivatives of erythromycin, modified in the cladinose ring, the desosamine ring, and the aglycone moiety (especially at C-9 of the aglycone), have been described. Their characterization contributed greatly to understanding the chemistry and structure – activity relationships of the macrolide antibiotics [163].

Erythromycin A (**37**) [*114-07-8*]

Picromycin (**41**), **narbomycin** (**42**), and **oleandomycin** (**43**) belong to the 14-membered lactones.

Picromycin (**41**) [*19721-56-3*] R = OH
Narbomycin (**42**) R = H

Oleandomycin (**43**) [*3922-90-5*]

3.5.3. 16-Membered Ring Macrolides

Stereochemical structures of carbomycins, leucomycins, spiramycins, and other macrolides have been disclosed by extensive chemical studies [164], [165]. These compounds have a formylmethyl group at C-6 and two conjugated double bonds in the 16-membered lactone ring. They differ only in the nature of the acyl substituents at C-3 and C-4. For instance, the leucomycin complex (kitasamycin), produced by *Streptomyces kitasatoensis* [166] is a mixture of ten similar components. These are **leucomycin A_1** (**44**, turimycin H_5), **leucomycin A_3** (**45**, josamycin, YL-704A_3 or platenomycin A_3), **leucomycin A_4** (**46**), **leucomycin A_5** (**47**), **leucomycin A_6** (**48**, YL-704B_3 or platenomycin B_3), **leucomycin A_7** (**49**), **leucomycin A_8** (**50**), **leucomycin A_9** (**51**), **leucomycin U** (**52**), and **leucomycin V** (**53**) [164], [167].

The spiramycins (foromacidins) produced by *Streptomyces ambofaciens* [168] have been separated into three components, namely **spiramycin I** (**54**), **spiramycin II** (**55**), and **spiramycin III** (**56**).

Many other macrolides, such as **rosamicin** [169], [170], **cirvamycin A_1** [171], [172], **juvenimicin A_2, juvenimicin A_4** [173], [174], **deltamycin** [175], **carbomycin** [176], [177], **angolamycin** [178], **tylosin** (**57**) [179–181], and the **mycinamicins** [182], [183], belong to this class.

Since 1950, the structures of more than 90 macrolides have been elucidated, and this knowledge has had a great impact on modern organic synthesis. The classification of the above-mentioned macrolides according to ring size is useful, but very schematic. There is a marked change in the antibiotic activity spectrum corresponding to changes in the ring size, even though many of the substituents and the degree of unsaturation differ considerably.

Macrolides with ca. 10 – 16 ring members are very strongly antibacterial, as are the smaller lactones. Because there is no cross-resistance among these macrolides, they are mainly used to treat bacterial infections that are resistant to other antibiotics.

Macrolides with ca. 16 – 40 ring members show very little activity against bacteria, often

[*22875-15-6*]

none at all, but they are highly effective against fungi, yeasts, etc.

The very large macrolides are highly effective against not only fungi, but also viruses and tumors.

3.6. Ansamycins

The ansamycins are a clinically important class of antibiotics with a characteristic structure. They have an aliphatic "ansa" bridge that connects two nonadjacent positions of an aromatic system [184]. The name "ansamycin" is based on the term "ansa compounds" [185]. Ansamycins are classified into two groups based on the nature of the aromatic moiety, i.e., benzoquinoid and naphthoquinoid ansamycins. Geldanamycin and maytansinoids belong to the benzoquinoid ansamycins and are studied as potential antitumor agents. The naphthoquinoid ansamycins include rifamycins, tolypomycins, streptovaricins, halomicins, and naphthomycin. The naphthoquinoid ansamycins are the major group of known ansamycins.

The rifamycins, produced by *Nocardia mediterranei,* have great therapeutic value [186, 188]. Their chemistry is very similar to that of the macrolides. After many attempts to separate, isolate, and purify the naturally occurring rifamycins, **rifamycin B** (**58**), **rifamycin O** (**59**), and **rifamycin S** (**60**) were found among the fermentation products. Rifamycin B was moderately effective against gram-positive bacteria. The oxidation of rifamycin B gave rifamycin O, which can be hydrolyzed to the more active rifamycin S. The latter can be reduced to **rifamycin SV** (**61**) using ascorbic acid. Rifamycin SV is converted, through its formyl derivative (**62**), to the therapeutically important **rifampicin** (**63**). In order to obtain an antibiotic with a broader spectrum and good oral absorption characteristics, thousands of derivatives of rifampicin have been prepared. Ri-

[*1401-69-0*]

famycins B, O, and S all are used as starting materials for the modifications. The rifampicins have strong biological activity against gram-positive microorganisms and mycobacteria, particularly *Mycobacterium tuberculosis* [189–191]. Most of the ansamycins are weakly active against viruses, and certain derivatives, such as **3-formylrifamycin S** (**62**), have been found to be active against certain tumors. No cross-resistance of the ansamycins to most of the other antibiotics has been observed.

3.7. Peptides

The various important functions of the living organism are frequently mediated by oligopeptides and proteins, which exist in the most diverse structures. It is therefore not surprising that a large number of low molecular mass peptides, oligopeptides, and protein-like substances are found among the antibiotics of microbial origin. Although peptide antibiotics consist of amino acids linked by peptide bonds, they differ from the proteins and peptides of higher animals and plants in many respects [192]. The following characteristics frequently are found in the peptide antibiotics:

1) Molecular masses of the antibiotics are smaller (in the range of 500 – 1500) than those of peptide hormones, which are frequently much larger.
2) The antibiotics contain some uncommon amino acids that are not found in proteins and peptide hormones of animal or plant origin. The usual amino acids are infrequently detected or are found in modified forms.
3) Lipids and other moieties not of amino acid character are found in many peptide antibiotics.
4) The peptide antibiotics frequently contain D-amino acid residues, whereas peptides of

plant and animal origin consist solely of L-amino acid residues.

5) Virtually all of the peptide antibiotics resist hydrolysis by proteolytic enzymes, which are otherwise effective in hydrolyzing peptides of plant and animal origin.
6) The antibiotics are often cyclic peptides.
7) Families of closely related peptide antibiotics are frequently produced by the same microorganism.

3.7.1. The Bleomycin Group

The bleomycins, a group of glycopeptide antibiotics produced by *Streptomyces verticillus* [193], make up one of the most widely used groups of antitumor antibiotics, effective against squamous cell carcinoma and malignant lymphoma. Extensive degradation studies have shown the main structural features to be a peptide containing unusual amino acid residues and a disaccharide of uncommon sugars. The complete structure has been elucidated by chemical studies and X-ray crystallographic analysis of P-3A, a biosynthetic intermediate structurally related to bleomycin [194], [195]. This structure has been verified by the total synthesis of **bleomycin A_2** (**67**). The naturally occurring bleomycins are obtained in copper-chelated form as a mixture of congeners that differ only in the substituents at the *C* terminus of **bleomycinic acid** (**64**), the common structural unit. Among these are **bleomycin A_1** (**65**), **demethylbleomycin A_2** (**66**), **bleomycin A_2** (**67**), **bleomycin $A_{2\prime-a}$** (**68**), **bleomycin $A_{2\prime-b}$** (**69**), **bleomycin $A_{2\prime-c}$**(**70**), **bleomycin A_5** (**71**), **bleomycin A_6** (**72**), **bleomycin B_1** (**73**), **bleomycin B_2** (**74**), and **bleomycin B_4**

[*65057-91-2*]
R = $NH(CH_2)_3NH(CH_2)_4NH_2$

(**75**). Metal-free bleomycin can be prepared by treatment with hydrogen sulfide. A mixture of metal-free bleomycins consisting mainly of A_2 (55 – 70 %) and B_2 (25 – 32 %) has been used for clinical treatment because the mixture has an effect superior to that of A_2 alone on human squamous cell carcinoma. The copper ion in bleomycin is replaced by iron after penetration into cells. A bleomycin – iron complex that exerts antitumor activity is formed. More than 300 bleomycin analogs have been prepared by chemical modifications or fermentations. **Pepleomycin** (**76**), possessing improved properties, has been brought into clinical use [196] and the **tallysomycins A and B**, **77** and **78**, respectively, are similar glycopeptides [197], [198].

3.7.2. The Gramicidin Group

Generally speaking, peptide antibiotics with simple straight-chain structures play a minor role and are mentioned here only for review purposes. However, peptide antibiotics with cyclic structures, which often contain D-amino acids, are of considerable importance. The usual nomenclature is used here for the constituents of the amino acids: Ala = alanine; Asp = asparagine; Cys = cysteine; Dab = α,γ-diaminobutyric acid; Glu = glutamic acid; Gly = glycine; His = histidine; Ileu = isoleucine; Leu = leucine; Lys = lysine; Orn = ornithine; Phe = phenylalanine; Pro = proline; Thr = threonine; Trp = tryptophan; Tyr = tyrosine; Val = valine; Meval = *N*-methylvaline; Sar = sarcosine; Ser = serine; MOA = 6-methyloctanoic acid; IOA = isooctanoic acid. The arrow indicates the direction of the amide bond between the amino acids. Thus, the arrow begins where the carbonyl group attaches and ends where the amino group attaches (– CO – NH →).

The gramicidin group consists of a series of open chain peptides and a series of cyclic peptides. Clinically important **gramicidin S** (**79**) was isolated from a strain of *Bacillus brevis* [199].

3.7.3. The Polymyxins

Among the polymyxins, **polymyxins B, D, and E** are of particular importance. The **colistins A and B** correspond to **polymyxins E_1 and E_2,** respectively, as shown in **80** [200]. These are active only against gram-negative bacteria.

80

	R	X	Y	Z
Polymyxin A_1 (M1) [*65454-50-4*]	MOA	D-Dab	D-Leu	Thr
Polymyxin A_2 (M2) [*65454-51-5*]	IOA	D-Dab	D-Leu	Thr

Polymyxin E_2 (colistin B) [*7239-48-7*]	IOA	Dab	D-Leu	Leu

Dab = α, γ-diaminobutyric acid; MOA = (+)-6-methyloctanoic acid; IOA = isooctanoic acid

3.7.4. The Bacitracins

Bacitracin, produced by *Bacillus subtilis* [201] and *Bacillus licheniformis* [202], is active against gram-positive bacteria. After extensive study on the chemistry of bacitracins, a revised structure was proposed for **bacitracin A** (**81**) [203].

Bacitracin A (**81**)
[*1402-99-9*]

3.7.5. Large-Ring Peptide Antibiotics Containing Lactone Linkages

This important group can be classified with macrolide antibiotics because it contains a lactone moiety, but it is more properly regarded as a group of cyclic peptides. These peptides generally contain about 16- to 19-membered rings, including many amide bonds and lactone linkages. There are no C–C double bonds in the ring.

3.7.6. The Actinomycin Group

These cyclic peptide antibiotics are also known as chromopeptide antibiotics. The **actinomycins** (**82**), first isolated by WAKSMAN in 1940 from *Streptomyces antibioticus,* are of interest because they have found use in therapy of tumors, particularly Wilm's tumor (see next page).

They are also used as a biochemical tool because of their specific inhibition of DNA-primed RNA synthesis. Structurally they have two pentapeptide lactone rings attached to a phenoxazinone chromophore. Several of the actinomycins isolated were found to be identical and the nomenclature is confusing. For example, actinomycin D and actinomycin C_3 are also known as dactinomycin and cactinomycin, respectively [204].

3.7.7. Other Peptide Antibiotics

There are many peptide antibiotics derived from *Streptomyces* species. Among these are amphomycin, capreomycin, distamycin, the enduracidins, mikamycin, neocarzinostatin (antitumor), stendomycin, viomycin, and virginiamycin.

3.8. Other Important Antibiotics and Intermediates

Cycloheximide (**83**) is produced by *Streptomyces griseus* [205]. It is highly effective against fungi and is therefore used mainly for plant protection. The analogs streptovitacin, naramycin B, and streptimidone have also been isolated, and also are called glutarimide antibiotics because of their common structural moiety.

Cycloheximide (**83**)

Cycloserine (**84**) (**oxymycin, seromycin, orientomycin**) is the simplest antibiotic, D-4amino-3-isoxazolidine, isolated from many *Streptomyces* species [206]. Cycloserine is now produced only synthetically and used particularly for tuberculosis of the lungs and for leprosy with *p*-aminosalicylic acid (PAS) or isonicotinic acid hydrazide (INH).

Cycloserine (**84**)
[*68-41-7*]

Variotin (**85**) (**pecilocin**) is produced by *Paecilomyces varioti* [207]. It is an oily, ester-like substance with an aromatic odor and is particularly active against fungi. Variotin is used against trichophytes.

Variotin (**85**)
[*19504-77-9*]

Sarkomycin A (**86**) is produced by *Streptomyces erythrochromogenes* [208]. It is active not only as an antibiotic but also as an antitumor agent.

Sarkomycin (**86**)
[*489-21-4*]

Novobiocin, isolated from a culture filtrate of *Streptomyces nieveus,* has the structure **87**, consisting of the aglycone, novobiocic acid, and 3-*O*-carbamoylnoviose. The monosodium or calcium salt is used in therapy and is active mainly against gram-positive bacteria [209].

Novobiocin (**87**)
[*303-81-1*]

Griseofulvin (**88**) is produced by *Penicillium griseofulvum, P. janczewskii,* and *Nigrospora oryzae.* It is unique in possessing the spirocarbon moiety [210], [211]. Griseofulvin is very active against fungi, and it is used orally to treat fungal infections of human skin.

Griseofulvin (**88**)
[*126-07-8*]

Chloramphenicol (**89**), the first of the so-called broad-spectrum medicinal antibiotics, was originally obtained from *Streptomyces venezuelae* in 1947 [212]. It is now manufactured by a chemical process, and the parent compound and its esters are commercially available. Chloramphenicol is active against rickettsia, chlamydiae, and mycoplasmas, as well as a wide range of gram-positive and gram-negative bacteria. However, use is limited by the risk of bone marrow damage or aplastic anemia at too high or too prolonged an application [213].

Chloramphenicol (**89**)
[*56-75-7*]

Mitomycins (**90–93**) are a group of unique chemical structures in which three different carcinostatic functions – aziridine, carbamate, and quinone – are arranged around a pyrro[1,2-*a*]indole nucleus [214]. The first mitomycins were discovered in 1956 by Hata in a culture filtrate of *Streptomyces caespitosus.* These compounds, designated mitomycins A and B, show highly potent antibacterial activity and moderate antitumor activity, but they are quite toxic in mice. In 1958, mitomycin C, an extremely valuable antitumor drug, was isolated from *Streptomyces caespitosus* [215], [216]. In 1960, another mitomycin, porfiromycin (**93**), was isolated from *Streptomyces ardus.*

Name	X	Y	Z
Mitomycin A (**90**) [*4055-39-4*]	OCH_3	OCH_3	H
Mitomycin B (**91**) [*4055-40-7*]	OCH_3	OH	CH_3
Mitomycin C (**92**) [*50-07-7*]	NH_2	OCH_3	H
Porfiromycin (**93**) [*801-52-5*]	NH_2	OCH_3	CH_3

Fumagillin (**94**) is a useful polyene antibiotic; feeding it to honeybees with natural *Nosema apis* infections suppressed the disease and led to considerably increased honey production [217].

Fumagillin (**94**)
[*23110-15-8*]

Monensins (**95**) are useful polyether antibiotics that control infections of *Coccidia*. They are particularly important to the poultry industry [218].

Monensin (**95**)
[*17090-79-8*]

Pyrrolnitrin (**96**), isolated from *Pseudomonas* species, is highly active against fungi, particularly trichophyte species.

Pyrrolnitrin (**96**)
[*1018-71-9*]

Fosfomycin (**97**) is unique in possessing a simple epoxide ring and has a broad activity spectrum against gram-positive and gram-negative bacteria [219].

Fosfomycin (**97**)
[*23155-02-4*]

Fusidic acid (**98**) has a steroidal skeleton, but it is markedly different from the usual steroid hormones in biological activity. Fusidic acid has been isolated from *Fusidium coccineum* and is particularly active against *Staphylococcus, Clostridium, Neisserias, Corynebacterium diphtheriae,* and *Mycobacterium tuberculosis* [220].

Fusidic acid (**98**)
[*6990-06-3*]

d-(*p*-Hydroxyphenyl)glycine (d-HPG) is widely used in large amounts as an important intermediate for the synthesis of amoxicillin and several other semisynthetic β-lactam antibiotics.

Industrially, D-HPG has been produced by resolving the racemic DL-HPG obtained by the

usual nonenzymatic synthesis. The optical resolution by means of fractional crystallization of the corresponding diastereomeric salt or by the predominant crystallization of the corresponding aromatic sulfonic acid salt are typical methods. However, these methods suffer disadvantages. The former requires multistep reactions and an expensive resolving agent.

The optical purity of the product is not very high. The yield obtained from one cycle of the latter resolution method is very low, and both methods require racemization and recyclization steps in the optical resolution process in order to increase the total yield of D-HPG.

The process developed by YAMADA et al. involves subjecting DL-5-(*p*-hydroxyphenyl)hydantoin (DL-HPH) to an enzymatic asymmetric hydrolysis utilizing microorganisms [221]. A new method of synthesizing DL-HPH has also been developed [222]. Thus, a high-purity D-HPG is produced industrially as shown in the sequence at the top of this page.

The substrate (DL-HPH) for the enzymatic reaction is synthesized starting with relatively inexpensive basic materials: phenol, glyoxylic acid, and urea. The enzymatic reaction hydrolyzes the hydantoin stereospecifically to afford the acid with the D configuration. The remaining substrate with the L configuration is automatically racemized under enzymatic reaction conditions. Consequently, DL-HPH can be quantitatively transformed into the desired acid, D-HPG. In this manner a very effective optical resolution is conducted kinetically. The D-*N*-carbamoyl(*p*-hydroxyphenyl)glycine thus otained is easily converted to D-HPG by treatment with nitrous acid.

As has been mentioned, the process for preparing D-HPG has been greatly simplified and provides D-HPG of very high optical purity when the enzymatic reaction is used.

This novel process has been developed industrially by Kanegafuchi Chemical Industry Company.

d-Phenylglycine is widely used in large quantity as the side chain that makes ampicillin and cephalexin orally acceptable. Industrially, D-phenylglycine has been produced by a conventional resolution method or by kinetic resolution with acylase. Another enzymatic procedure has been developed by YAMADA et al. [221], [222] as shown below.

Enediynes. A class of antitumor antibiotics possessing characteristic enediynechromophores have been isolated [223]. These include neocarzinostatin (**240**) [224], [225], calicheamicins (**241**) [226], [227], esperamicins (**242**) [228], [229], dynemicin A (**243**) [230], C-1027 (**244**) [231], [232], kedarcidin (**245**) [233–236], and maduropeptin (**246**) [237].

Neocarzinostatin was isolated from *Streptomyces carzinostaticus* Var. F-41 as a complex of a chromophore and an apoprotein [224], [225].

240 Neocarzinostain chromophore

241 Calicheamicin γ'_1

242 Esperamicin A_1

The role of the apoprotein is to transport and stabilize the chromophore that is responsible for the anticancer activity of neocarzinostatin coming mainly from its capability to cleave DNA. The DNA damage is initiated by nucleophilic attack at C12 of neocarzinostatin chromophore by a sulfur nucleophile leading to the formation of a labile cumulene intermediate that undergoes a facile cycloaromatization [238]. The resulting biradical abstracts hydrogen atom of the deoxyribose of DNA to induce degradation. A polymer conjugated derivative of neocarzinostatin was prepared and administered via the tumor-feeding artery showing increased stability in blood and the immunogenicity was much lower than the parental neocarzinostatin [239]. Similar biradical formation via the Bergman cy-

246 Maduropeptin chromophore

clization of the other enediyne class antibiotics has been proposed [223].

4. Individual Antibiotics Use

Benzylpenicillin potassium [*113-98-4*] (**99**), penicillin G potassium, $C_{16}H_{17}KN_2O_4S$, M_r 372.49.

99

Benzylpenicillin potassium was the first crystalline penicillin produced on an industrial scale [22], [24]. It is produced in the pure state by the addition of phenylacetate to a culture of *Penicillium chrysogenum.* The crystalline benzylpenicillin potassium contains 1598 U/mg.

Benzylpenicillin procaine [*6130-64-9*] (**100**), penicillin G procaine, $C_{16}H_{18}N_2O_4S \cdot C_{13}H_{20}N_2O_2 \cdot H_2O$, M_r 588.73.

100

Benzylpenicillin procaine was developed as a dilatorily acting benzylpenicillin, only slightly soluble in water. It has been used with peanut oil or carboxymethylcellulose as an oil suspension or an aqueous suspension, respectively [240].

Benzylpenicillin benzathine [*41372-02-5*] (**101**), penicillin G benzathine, $(C_{16}H_{18}N_2O_4S)_2 \cdot C_{16}H_{20}N_2 \cdot 4H_2O$, M_r 981.21.

101

Benzylpenicillin benzathine was developed as a dilatorily acting benzylpenicillin that maintains an effective serum concentration for 2 days following a single intramuscular injection of 600000 U. It is also used as an orally active benzylpenicillin because it is only slightly affected by a patient's meal [241].

Phenoxymethylpenicillin [*87-08-1*], (**102**), penicillin V, $C_{16}H_{18}N_2O_5S$, M_r 350.40.

102

Phenoxymethylpenicillin was produced in the culture broth of *Penicillium chrysogenum* when phenoxyacetic acid was added to the medium at Biochemie in 1953 [242]. It is more stable against acid than benzylpenicillin and is used as an orally active penicillin. Its therapeutic applications are the same as those of benzylpenicillin.

Phenoxymethylpenicillin potassium [*132-98-9*], (**103**), penicillin V potassium, $C_{16}H_{17}KN_2O_5S$, M_r 388.49.

Phenoxymethylpenicillin potassium was first obtained at Lilly Research Laboratories in 1948,

103

following the addition of phenoxyacetic acid to a culture of *Penicillium chrysogenum*. Its industrial-scale production was established in 1953 [243]. Its usefulness as an orally active penicillin was suggested by Spitzy et al. in 1955. It is less hygroscopic and much more stable against gastric acid than benzylpenicillin, and it has been used orally for therapy of infections caused by *Streptococcus, Staphylococcus,* and other gram-positive bacteria as well as *Neisseria* and *Leptospira*.

Phenethicillin potassium [*132-93-4*], (**104**), $C_{17}H_{19}KN_2O_5S$, M_r 402.52.

104

Phenethicillin was the first member of the semisynthetic penicillin class of antibiotics to be introduced in clinics. This drug was synthesized in 1960 by Bristol-Myers in collaboration with Beecham Research Laboratories starting with 6-aminopenicillanic acid [244]. It is as stable against gastric acid as phenoxymethylpenicillin and is used orally for therapy of gram-positive and *Neisseria* infections.

Propicillin [*551-27-9*], (**105**), $C_{18}H_{22}N_2O_5S$, M_r 378.45.

105

Propicillin was synthesized by a collaboration of Beecham Research Laboratories with Bristol-Myers Laboratories in 1961 starting with 6-aminopenicillanic acid [245]. It is stable against gastric acid and shows three- to fourfold higher serum concentrations than phenoxymethyl-penicillin when administered orally. Its antibacterial spectrum and activity are almost the same as those of phenoxymethylpenicillin. Propicillin has been used for therapy of infections caused by *Streptococcus, Staphylococcus,* and *Neisseria.*

Carbenicillin disodium [*4800-94-6*], (**106**), $C_{17}H_{16}N_2Na_2O_6S$, M_r 422.37.

106

Carbenicillin was synthesized by Brain et al. of Beecham Research Laboratories in 1965. It was the first synthetic penicillin to show activity against *Pseudomonas aeruginosa* [246]. Although its activity against the microorganism is not strong (MIC = 25 – 100 µg/mL), it is widely

used against *P. aeruginosa* infections because of its low toxicity and the lack of other antibiotics suitable for use against this microorganism. Carbenicillin is mainly used clinically to treat urinary tract and respiratory tract infections and sepsis caused by *Proteus, Escherichia coli, Klebsiella,* and *Pseudomonas aeruginosa.*

Carbenicillin phenyl sodium [*21649-57-0*], (**107**), carfecillin, $C_{23}H_{21}N_2NaO_6S$, M_r 476.49.

107

Carbenicillin phenyl was synthesized by Beecham Research Laboratories in 1966 as an orally active carbenicillin [247]. It is hydrolyzed to carbenicillin by intestinal esterase and thus acts the same when administered orally. The phenol produced by the hydrolysis is conjugated and excreted in urine.

Carbenicillin indanyl sodium [*26605-69-6*], (**108**), carindacillin, $C_{26}H_{25}N_2NaO_6S$, M_r 516.55.

108

Carbenicillin indanyl was synthesized by Pfizer in 1972 as an orally active carbenicillin [248]. It shows strong activity against a variety of bacteria in vitro, and, when administered orally, it behaves as carbenicillin after being hydrolyzed by intestinal esterase.

Sulbenicillin [*34779-28-7*], (**109**), $C_{16}H_{18}N_2O_7S_2$, M_r 414.46.

109

Sulbenicillin was synthesized by Takeda Chemical Industries in 1968 [249]. It shows slightly lower activity against gram-positive bacteria, almost the same activity against gram-negative bacteria, and slightly higher activity against anaerobic bacteria in comparison with carbenicillin. Sulbenicillin has been used by intravenous and intramuscular administration for therapy of sepsis, bacterial endocarditis, pyoderma, urinary tract and respiratory tract infections, and other infections caused by *Staphylococcus, Streptococcus, Klebsiella, Proteus, Enterobacter, Citrobacter, Escherichia coli* and *Haemophilus influenzae.*

Ticarcillin disodium [*4697-14-7*], (**110**), $C_{15}H_{14}N_2Na_2O_6S_2$, M_r 428.40.

110

Ticarcillin was synthesized by Beecham Research Laboratories in 1971. The phenyl residue of carbenicillin was replaced by the 3-thienyl moiety [250]. Ticarcillin shows almost the same activity as carbenicillin against gram-positive bacteria and a twofold higher activity against gram-negative bacteria. Its in vivo activity against *Pseudomonas aeruginosa* infections in mice is fourfold higher than that of sulbenicillin. Ticarcillin is used to treat sepsis, urinary tract infections, and serious *Pseudomonas aeruginosa, Escherichia coli, Proteus,* and *Enterobacter* infections in leukemic and other cancer patients.

Methicillin sodium [*7246-14-2*], (**111**), meticillin, $C_{17}H_{19}N_2NaO_6S \cdot H_2O$, M_r 420.42.

111

Methicillin was synthesized independently by Bristol-Myers Laboratories and Beecham Research Laboratories in 1960 [251]. It was the

first member of the penicillinase-stable semisynthetic penicillin class of antibiotics to be introduced clinically. This antibiotic is a parenteral penicillin having an antibacterial spectrum similar to that of benzylpenicillin. Although its activity against benzylpenicillin-sensitive bacteria is about 1/3 to 1/50 that of benzylpenicillin, it shows strong activity against benzylpenicillin-resistant strains because of its stability toward penicillinase. Methicillin has been used for therapy of respiratory tract and urinary tract infections, sepsis, and gynecological and other infections caused by benzylpenicillin-resistant bacteria.

Oxacillin sodium [*7240-38-2*], (**112**), $C_{19}H_{18}N_3NaO_5S \cdot H_2O$, M_r 441.43.

112

Oxacillin was synthesized by Bristol-Myers Laboratories in 1961 starting with 6-aminopenicillanic acid [252]. It was the first orally active and penicillinase-stable semisynthetic penicillin to be introduced clinically. Oxacillin is slightly less stable against gastric acid and shows a lower serum concentration than phenoxymethylpenicillin, but it is highly active against phenoxymethylpenicillin-resistant *Staphylococcus aureus.* Oxacillin has been used by oral and intramuscular administration for therapy of respiratory tract, urinary tract, gynecological, and other infections caused by benzylpenicillin-resistant bacteria.

Cloxacillin sodium [*7081-44-9*], (**113**), $C_{19}H_{17}ClN_3NaO_5S \cdot H_2O$, M_r 475.89.

113

Cloxacillin was synthesized by Beecham Research Laboratories in 1962 starting with 6-aminopenicillanic acid [253]. It was the first semisynthetic penicillin with a halogen atom in the side chain to be used clinically. It shows 5- to 20-fold stronger activity than methicillin and is twice as active as oxacillin against *Staphylococcus aureus*, including benzylpenicillin-resistant strains. Cloxacillin is highly stable against penicillinase and well absorbed by oral administration. It has been widely used, by oral and intramuscular administration, to treat internal, surgical, gynecological, and other infections caused by both benzylpenicillin-sensitive and benzylpenicillin-resistant bacteria.

Dicloxacillin [*3116-76-5*], (**114**), $C_{19}H_{17}Cl_2N_3O_5S$, M_r 470.33.

114

Dicloxacillin was synthesized by Bayer in 1965 starting with 6-aminopenicillanic acid [254]. It is a penicillinase-stable and orally active semisynthetic penicillin and shows higher and longer serum concentrations than cloxacillin when administered orally. Dicloxacillin is used orally, either alone or in combination with ampicillin, to treat various infections, including those caused by benzylpenicillin-resistant bacteria.

Flucloxacillin [*5250-39-5*], (**115**), floxacillin, $C_{19}H_{17}ClFN_3O_5S$, M_r 453.88.

115

Flucloxacillin was synthesized by Beecham Research Laboratories in 1962 as a penicillinase-stable and orally active semisynthetic penicillin [255]. It shows almost the same activity as dicloxacillin, and it has slightly higher serum and tissue concentrations than dicloxacillin. This drug has been used to treat pyoderma, sepsis, and postoperative infections as well as ear and nose, respiratory tract, and other infections caused by *Staphylococcus* and *Streptococcus*, including benzylpenicillin-resistant strains.

Ampicillin [*69-53-4*], (**116**), aminobenzyl penicillin, $C_{16}H_{19}N_3O_4S$, M_r 349.41.

116

Ampicillin was synthesized by Beecham Research Laboratories in 1961 and evaluated for its anti-gram-negative activity by ROLINSON et al. [256]. It was the first semisynthetic penicillin showing strong activity against gram-negative bacilli. Although it is hydrolyzed by bacterial penicillinase, it is active against *Escherichia coli, Shigella, Proteus mirabilis,* and *Haemophilus influenzae* and is used very widely as an oral antibiotic. Ampicillin also is used by injection for serious infections.

Mezlocillin [*51481-65-3*], (**117**), $C_{21}H_{25}N_5O_8S_2$, M_r 539.59.

117

Mezlocillin was synthesized by Bayer in 1974 [257]. The NH_2 residue of ampicillin was acylated. Mezlocillin is a member of the so-called ureidopenicillins and shows two- to eightfold greater activity against *Citrobacter, Enterobacter, Klebsiella, Escherichia coli,* and *Haemophilus influenzae* than ampicillin, carbenicillin, or sulbenicillin. Its activity against gram-positive bacteria is almost the same as that of carbenicillin. Mezlocillin is used by intravenous administration for therapy of sepsis, meningitis, and respiratory tract, urinary tract, and abdominal infections.

Piperacillin sodium [*59703-84-3*], (**118**), $C_{23}H_{26}N_5NaO_7S$, M_r 539.55.

118

Piperacillin was synthesized by Toyama Chemicals Company in 1976 by acylation of the amino residue of ampicillin [258]. It shows excellent activity against a wide range of gram-positive and gram-negative bacteria and has been used as the most potent semisynthetic penicillin. Piperacillin is administered intravenously or intramuscularly for therapy of sepsis, meningitis, respiratory and urinary tract infections, and for abdominal infections caused by *Staphylococcus, Streptococcus, Escherichia coli, Klebsiella, Haemophilus influenzae, Serratia marcescens, Pseudomonas aeruginosa, Proteus, Enterobacter, Citrobacter,* and *Bacteroides.*

Amoxicillin [*61336-70-7*], (**119**), amoxycillin, $C_{16}H_{19}N_3O_5S \cdot 3\,H_2O$, M_r 419.46.

119

Amoxicillin was synthesized by Beecham Research Laboratories in 1968 [259]. A hydroxyl group was introduced on the benzene ring of ampicillin. Amoxicillin shows about a twofold higher serum concentration than ampicillin when administered orally. It was shown by double-blind comparative studies with ampicillin that amoxicillin was as effective as ampicillin when administered at half the dose of ampicillin.

Ciclacillin [*3485-14-1*], (**120**), cyclacillin, $C_{15}H_{23}N_3O_4S$, M_r 341.43.

120

Ciclacillin was synthesized by Wyeth Laboratories in 1967 in the course of studies on the improvement of oral absorption of ampicillin [260]. Although its antibacterial activity is one-sixteenth to one-half that of ampicillin, it shows a four to tenfold higher oral absorption and higher urinary excretion. Ciclacillin shows less tendency than ampicillin to cause diarrhea and is used for therapy of pyoderma, wound infection, respiratory and urinary tract infections, as well as ear and nose, and other infections caused by *Staphylococcus, Streptococcus, Escherichia coli, Citrobacter, Klebsiella, Proteus,* and *Haemophilus influenzae.*

Hetacillin [*3511-16-8*], (**121**), $C_{19}H_{23}N_3O_4S$, M_r 389.48.

121

Hetacillin was synthesized by Bristol-Myers Laboratories in 1964. It shows activity as strong as that of ampicillin against a variety of gram-positive and gram-negative bacteria [261]. Hetacillin shows almost the same pharmacokinetic properties as ampicillin when administered orally and a later serum peak when given by intramuscular administration. When administered either orally or intramuscularly, it is hydrolyzed in vivo into ampicillin. Therefore, the clinical applications of hetacillin are the same as those of ampicillin.

Sulbactam sodium [*69388-84-7*], (**122**), $C_8H_{10}NNaO_5S$, M_r 255.22.

122

Sulbactam was synthesized by Pfizer Research Laboratories in 1977 in the course of screening for β-lactamase inhibitors [262]. It shows strong activity against penicillinase and moderate activity against cephalosporinase. Sulbactam itself shows activity against some gram-negative bacteria but no activity against most pathogenic bacteria. The use of sulbactam in combination with cefoperazone, which is partially hydrolyzed by penicillinase, is under study along with its use as an esterified complex with ampicillin (sultamicillin) for therapy of cefoperazone-ampicillin-resistant infections.

Talampicillin hydrochloride [*39878-70-1*], (**123**), ampicillin phthalidyl, $C_{24}H_{23}N_3O_6S \cdot HCl$, M_r 517.99.

123

Talampicillin was synthesized by Yamanouchi Pharmaceutical Co. in 1971 by esterifying the carboxylic acid group of ampicillin in order to improve the oral absorption [263]. When administered orally, it is hydrolyzed to ampicillin by intestinal esterase. Its bioavailability is two or more times as high as that of ampicillin, and it is used to treat the same infections as those for which ampicillin is used orally but in doses only half or one-third as large.

Bacampicillin hydrochloride [*37661-08-8*], (**124**), ampicillin ethoxycarbonyloxyethyl hydrochloride, $C_{21}H_{27}N_3O_7S \cdot HCl$, M_r 501.99.

124

Bacampicillin was synthesized by Ekström et al. of Astra Läkemedel in 1975 [264]. It is more stable against acid than ampicillin and more rapidly absorbed orally; its absorption is less affected by a patient's most recent meal than is the case for ampicillin. Bacampicillin is hydrolyzed by intestinal esterase after oral administration and then behaves the same as ampicillin. In double-blind comparison studies, bacampicillin was shown to be as effective as ampicillin when administered at half the dose.

Pivmecillinam [*32886-97-8*], (**125**), amdinocillin pivoxil, $C_{21}H_{33}N_3O_5S$, M_r 439.58.

125

Pivmecillinam was found by a series of studies at Leo in 1969 [265]. It is a derivative of 6β-formamidinopenicillanic acid and shows strong activity against gram-negative bacilli. Pivmecillinam is hydrolyzed by intestinal esterase and acts similarly to mecillinam after oral administration. Mecillinam shows weaker activity than ampicillin against gram-positive cocci but much stronger activity against a wide range of gram-negative bacilli [266].

Cephalexin [*23325-78-2*], (**126**), cefalexin, $C_{16}H_{17}N_3O_4S \cdot H_2O$, M_r 365.41.

126

Cephalexin was first synthesized in 1967 by Glaxo Research Laboratories [267] and first produced on an industrial scale by Eli Lilly & Co. in the same year. It is a deacetoxylated derivative of cephaloglycin that is not metabolized in vivo. When administered orally, it shows a much higher serum concentration and much lower tendency to induce diarrhea than cephaloglycin. Cephalexin has been used widely and is the most popular orally active antibiotic in the world for treatment of respiratory tract, urinary tract, surgical, ear and nose, and other infections caused by *Staphylococcus, Streptococcus, Escherichia coli, Klebsiella, Enterobacter,* and *Proteus.*

Cefaclor [*70356-03-5*], (**127**), $C_{15}H_{14}ClN_3O_4S \cdot H_2O$, M_r 385.83.

127

Cefaclor was found by Eli Lilly & Co. in 1976 in the course of studies on the improvement of synthetic procedures for cephalexin [268]. The intermediates with chlorine at the 3 position of the cephem nucleus have excellent antibacterial activity. Cefaclor was selected from among the various derivatives that differed at the 7 position because of its strong activity and high bioavailability following oral administration.

Cephaloglycin [*22202-75-1*], (**128**), cefaloglycin, $C_{18}H_{19}N_3O_6S \cdot 2\,H_2O$, M_r 441.46.

128

Cephaloglycin was synthesized by Lilly Research Laboratories in 1966 as the first member of the orally active cephalosporin C class of antibiotics [269]. Its activity against *Staphylococcus* and *Streptococcus* is one-fourth to one-half that of cephaloridin, a parenteral antibiotic, but against gram-negative bacteria it is almost the equal of cephaloridin. Cephaloglycin is readily absorbed by oral administration but is partially metabolized in vivo into deacetylcephaloglycin, which shows one-tenth to one-half as much activity. This antibiotic has been used in therapy of urinary tract infections and pyoderma, but it is being replaced by the newer orally active cephalosporins. Cephaloglycin often causes diarrhea, especially in children, and pediatric use is not allowed.

Cefadroxil [*66592-87-8*], (**129**), $C_{16}H_{17}N_3O_5S \cdot H_2O$, M_r 381.41.

129

Cefadroxil was found by Bristol-Myers Co. in 1976 [270]. A hydroxyl group was attached to the benzene ring of cephalexin. Like amoxicillin and ampicillin, cefadroxil shows almost the same antibacterial activity spectrum as cephalexin and superior oral absorption. Its in vivo activity is four to six times greater than that of cephalexin, and its half-life in serum is twice as long.

Cephradine [*38821-53-3*], (**130**), cefradine, $C_{16}H_{19}N_3O_4S$, M_r 349.41.

130

Cephradine was synthesized by the Squibb Institute of Medical Research in 1971 [271]. It shows almost the same antibacterial activity and pharmacokinetic properties as cephalexin. Cephradine has been used for therapy of urinary and respiratory tract infections caused by *Staphylococcus, Streptococcus, Escherichia coli, Klebsiella,* and *Proteus mirabilis.*

Cefroxadine [*51762-05-1*], (**131**), $C_{16}H_{19}N_3O_5S$, M_r 365.41.

131

Cefroxadine was synthesized by Ciba-Geigy in 1972. A methoxyl group replaced the methyl group of cephradine at the 3 position of the cephem nucleus [272]. Cefroxadine shows stronger activities than cephalexin, especially bactericidal and bacteriolytic activities, and it has better oral absorption that is less affected by a recent meal. Cefroxadine shows less renal toxicity than cephalexin in toxicological studies using animals.

Cephapirin sodium [*24356-60-3*], (**132**), cefapirin, $C_{17}H_{16}N_3NaO_6S_2$, M_r 445.45.

132

Cephapirin was synthesized by Bristol-Myers Laboratories in 1970 [273]. It shows almost the same in vitro antibacterial activity as cephalothin, but its in vivo effects are slightly greater than those of cephalothin. Like cephalothin, it is metabolized in vivo, and its deacetylated metabolite shows almost the same activity against gram-positive bacteria as cephalothin, but weaker activity against gram-negative bacteria. Cephapirin has been used for therapy of urinary tract infections and osteomyelitis caused by *Staphylococcus, Streptococcus,* and *Escherichia coli.*

Cephalothin sodium [*58-71-9*], (**133**), $C_{16}H_{15}N_2NaO_6S_2$, M_r 418.43.

133

Cephalothin, along with cephaloridine, was the first of the synthetic cephalosporin C class antibiotics to be introduced clinically. It was synthesized from 7-amino-cephalosporanic acid by Lilly Research Laboratories in 1962 [274]. Cephalothin shows strong activity against gram-positive and gram-negative bacteria and *Leptospira,* including benzylpenicillin-resistant strains. It has been used intravenously and intramuscularly to treat a variety of infections caused by *Staphylococcus, Streptococcus, Escherichia coli,* and *Neisseria*. The drug is metabolized in vivo, and the metabolite, deacetylcephalothin, is almost inactive.

Cephacetrile sodium [*23239-41-0*], (**134**), cefacetrile, $C_{13}H_{12}N_3NaO_6S$, M_r 361.31.

134

Cephacetrile was synthesized by Ciba-Geigy in 1970 [275]. It shows almost the same activity against gram-negative bacteria as cephalothin, but it has a higher activity against β-lactamase-producing *Escherichia coli.* Like cephalothin, it is metabolized partially by deacetylation in vivo. Cephacetrile has been used to treat sepsis and abdominal and respiratory tract infections caused by *Staphylococcus, Streptococcus, Escherichia coli,* and *Klebsiella pneumoniae,* but it is gradually being replaced clinically by the newer and more active cephalosporins.

Cefsulodin sodium [*52152-93-9*], (**135**), $C_{22}H_{19}N_4NaO_8S_2$, M_r 554.54.

135

Cefsulodin was synthesized by Takeda Chemicals Industries in 1974 by introducing the sulfobenzyl group, the same moiety as in sulbenicillin, at the 7 position of the cephem nucleus [276]. Its side chain at the 3 position is similar to that of cephaloridine except for the carbamoyl group. The introduction of these hydrophilic groups increases the activity against *Pseudomonas aeruginosa*, but it markedly decreases it against gram-positive and other gram-negative bacteria. Therefore cefsulodin is used as a specific antibiotic against infections caused by the opportunistic pathogen *P. aeruginosa.*

Cephaloridine [*50-59-9*], (**136**), cefaloridine, $C_{19}H_{17}N_3O_4S_2$, M_r 415.49.

136

Cephaloridine, along with cephalothin, was the first member of the synthetic cephalosporin C class of antibiotic, to be introduced clinically. It was synthesized, starting with 7-aminocephalosporanic acid, by Glaxo Research Laboratories in 1962 [277]. This drug shows strong activity against gram-positive and gram-negative bacteria and *Leptospira*, including benzylpenicillin-resistant strains. It has been given widely by intravenous, intramuscular, and intraspinal injection to treat a variety of infections caused by *Staphylococcus, Streptococcus, Neisseria, Klebsiella, Escherichia coli,* and other pathogens. Because of its renal toxicity and the development of newer and more active synthetic cephalosporins, its use is declining.

Cefatrizine [*51627-14-6*], (**137**), $C_{18}H_{18}N_6O_5S_2$, M_r 462.51.

137

Cefatrizine was synthesized by Bristol-Myers Co. and Smith Klein & French Laboratories in 1974 [278]. It shows two to four times higher activity against gram-positive and four to eight times higher activity against gram-negative bacteria than cephalexin. Cefatrizine also shows excellent oral absorption, and its in vivo activity is 30 to 500 times higher than that of cephalexin.

Cefoperazone sodium [*62893-20-3*], (**138**), $C_{25}H_{26}N_9NaO_8S_2$, M_r 667.66.

138

Cefoperazone was synthesized by Toyama Chemicals Co. in 1978. Except for the hydroxyl group, the side chain attached to the cephem nucleus is the same as that of piperacillin [279]. Cefoperazone shows excellent activity against gram-positive (except *Staphylococcus*) and gram- negative bacteria, including *Pseudomonas aeruginosa.* Its pharmacological characteristics are unique. Cefoperazone is excreted mainly in bile, and a concentration five to tenfold higher in bile than in serum is obtained. The transfer into cerebrospinal fluid is 10 – 30 % of the serum concentration; the half-life in serum is 2.0 – 2.6 h, and the degree of binding with serum protein is as high as 86.6 %.

Cefamandole [*34444-01-4*], (**139**), $C_{18}H_{18}N_6O_5S_2$, M_r 462.51.

139

Cefamandole was synthesized by Eli Lilly & Co. in 1972 [280]. It shows strong activity against *Proteus* (indole-positive) species, *Enterobacter*, and *Citrobacter,* against which the earlier cephalosporins, such as cephalothin and cefazolin, are inactive. The nafate (sodium salt of the *O*-formyl ester) has been used in the United States and Europe, and the sodium salt of cefamandole has been used in Japan by injection.

Cefotiam hydrochloride [*66309-69-1*], (**140**), $C_{18}H_{23}N_9O_4S_3 \cdot 2\,HCl$, M_r 598.56.

140

Cefotiam was synthesized by Takeda Chemicals Industries in 1977 as the first cephem derivative to introduce the aminothiazol group in the 7 side chain and the alkylated tetrazole group at the 3 side chain [281]. This drug shows greater antibacterial activity against gram-negative bacteria than the earlier cephalosporins, including *Enterobacter, Citrobacter,* and indole-positive *Proteus,* and it retains the same activity as they have against gram-positive organisms. Its excellent activity against *Klebsiella* and *Escherichia coli* is based on its ability to penetrate the cell. This is 3- to 70-fold greater than that of cephalothin or cefazolin.

Cefazolin sodium [*27164-46-1*], (**141**), $C_{14}H_{13}N_8NaO_4S_3$, M_r 476.50.

141

Cefazolin was synthesized by Fujisawa Pharmaceutical Co. in 1969 [282]. It was the first of the cephem antibiotics to introduce a thiadiazolylthiomethyl group at the 3 position and a tetrazole group at the 7 position in the side chain. Cefazolin is a parenteral cephem antibiotic showing better activity against gram-negative bacteria than cephalothin or cephaloridine. Its bactericidal activity, tissue distribution, and urinary excretion are excellent and it has wide clinical use.

Ceftizoxime sodium [*68401-82-1*], (**142**), $C_{13}H_{12}N_5NaO_5S_2$, M_r 405.39.

142

Ceftizoxime was synthesized by Fujisawa Pharmaceutical Industries in 1979 [283]. It possesses the (iminothiazolyl)methoxyiminomethyl group at the 7 position of the cephem nucleus, but there is no side chain at the 3 position. The compound shows excellent activity against gram-positive and gram-negative bacteria, behavior similar to that of cefotaxime. Unlike cefotaxime, however, it is not metabolized in vivo.

Cefotaxime sodium [*64485-93-4*], (**143**), $C_{16}H_{16}N_5NaO_7S_2$, M_r 477.45.

143

Cefotaxime was synthesized by Hoechst and Roussel-Uclaf in 1977 [284]. It was the first derivative of cephalosporin to introduce the methoxyimino and aminothiazole groups at the 7 position of the cephem nucleus. Although it shows unexpectedly low oral absorption, its excellent activity against a wide range of gram-positive and gram-negative organisms, including *Serratia, Enterobacter, Citrobacter,* and anaerobes, guided research and development of the newer synthetic cephems, the so-called third-generation cephalosporins.

Cefmenoxime hydrochloride [*75738-58-8*], (**144**), $(C_{16}H_{17}N_9O_5S_3)_2 \cdot HCl$, M_r 1059.59.

144

Cefmenoxime was synthesized by Takeda Pharmaceutical Co. in 1978 [285]. It contains aminothiazole and methoxyimino groups in the 7-acyl position and a methyltetrazole group at the 3 position of the cephem nucleus. Cefmenoxime has a wide activity spectrum against gram-positive and gram-negative bacteria, including anaerobes, except *Staphylococcus aureus.* Cefmenoxime is a member of the so-called third-generation cephalosporins, a recently introduced class of clinically important antibiotics.

Cefuroxime [*55268-75-2*], (**145**), $C_{16}H_{16}N_4O_8S$, M_r 424.39.

145

Cefuroxime was synthesized by Glaxo Laboratories in 1975 as the first cephem antibiotic with the methoxyimino group at the 7 position [286]. It is highly resistant to hydrolysis by cephalosporinase and is active against a variety of gram-negative bacteria, including indole-positive *Proteus, Enterobacter,* and *Citrobacter.* Cefuroxime is considered to be one of the so-called second-generation cephalosporins.

Ceftriaxone sodium [*74578-69-1*] (**146**), $C_{18}H_{16}N_8Na_2O_7S_3$, M_r 598.55.

146

Ceftriaxone was synthesized by Hoffmann-La Roche in 1981 [287]. The triazinyl moiety was introduced at the 3 position of the cephem nucleus. The same side chain as possessed by cefotaxime and the other so-called third-generation cephalosporins was retained at the 7 position. The antibacterial activity of ceftiaxone is almost the same as that of cefotaxime in vitro, but its in vivo activity is 10 to 100 times higher. Its most characteristic property is its seven to eight hour half-life in serum, the longest among the known cephem antibiotics.

Ceftazidime [*72558-82-8*], (**147**), $C_{22}H_{22}N_6O_7S_2$, M_r 546.58.

147

Ceftazidime was synthesized by Glaxo Laboratories in 1979 [288]. A new side chain, a carboxypropyloxyimino group with an aminothiazolyl group, was attached at the 7 position of the cephem nucleus. The compound shows excellent activity against *Pseudomonas aeruginosa,* indole-positive *Proteus* spp., *Enterobacter cloacae,* and *Serratia,* which are called opportunistic pathogens. Its activity against clinically isolated *P. aeruginosa* strains was found to be twofold higher than that of cefsulodin, a specific antibiotic widely used against that microorganism. Unlike cefsulodin, it shows balanced activity against other gram-negative bacteria and *Streptococcus.*

Cefoxitin [*35607-66-0*], (**148**), $C_{16}H_{17}N_3O_7S_2$, M_r 427.46.

148

Cefoxitin was synthesized by Merck Sharp & Dohme Research Laboratories in 1972 as the first clinically applicable cephamycin; it was derived from a cephamycin component obtained from *Streptomyces lactamdurans* [289]. The drug is slightly hydrolyzed by β-lactamases

and shows great activity against gram-negative bacteria and anaerobes.

Cefmetazole [*56796-20-4*], (**149**), $C_{15}H_{17}N_7O_5S_3$, M_r 471.54.

149

Cefmetazole was synthesized by Sankyo Co. in 1976 starting with a biosynthetic cephamycin [290]. It shows excellent activity against *Serratia* and *Proteus*, against which cefazolin is not active, and it has stronger activity than cefoxitin, another derivative of cephamycin. Cefmetazole is active against anaerobes and resistant to β-lactamase, but it is not active against *Pseudomonas aeruginosa.*

Cefotetan [*69712-56-7*] (**150**), $C_{17}H_{17}N_7O_8S_4$, M_r 575.62.

150

Cefotetan was synthesized by Yamanouchi Pharmaceutical Co. in 1979 starting with oganomycin, a cephamycin, produced by *Streptomyces oganoensis* YG19Z [291]. Its 7β side chain, 1,3-dithietan, is unique and contributes greatly to its strong activity against gram-negative bacteria, including *Serratia, Citrobacter, Enterobacter,* indole-positive *Proteus,* and anaerobes. Its half-life in the serum is as long as three hours, and about 90 % of it is excreted in the urine.

Latamoxef [*64953-12-4*], (**151**), disodium moxalactam, $C_{20}H_{18}N_6Na_2O_9S$, M_r 564.44.

151

Latamoxef was synthesized by Shionogi Pharmaceuticals in 1975 starting with benzylpenicillin and using a novel drug design [292]. The oxacephem nucleus, in which the sulfur atom had been replaced by oxygen, was substituted with a methoxyl group at the 7α position, as in the cephamycins. A carboxyl moiety and a hydroxybenzyl group were added at the 7β position, as in carbenicillin, and a methyltetrazolylthiomethyl group was attached at the 3 position. These substitutions resulted in a strong activity against gram-negative bacteria and a high resistance to the action of β-lactamase, along with excellent activity against *Pseudomonas aeruginosa,* even though the compound has no activity against *Staphylococcus aureus.*

Clavulanic acid [*58001-44-8*], (**152**), $C_8H_9NO_5$, M_r 199.16.

152

Clavulanic acid was found in the culture broth of *Streptomyces clavuligerus* by Beecham Research Laboratories in 1976 [293]. It was the first β-lactamase inhibitor. This antibiotic shows weak antibacterial activity against gram-positive and gram-negative organisms but strong inhibitory activity against the β-lactamase produced by ampicillin-resistant bacteria. Clavulanic acid is used orally in combination with amoxicillin and with ticarcillin by injection to enhance the activities of these antibiotics against resistant infections.

Imipenem [*64221-86-9*], (**153**), *N*-formimidoylthienamycin.

Thienamycin: R = H
$C_{11}H_{16}N_2O_4S$, M_r 272.33
N-Formimidoylthienamycin: R = -CH=NH
$C_{12}H_{17}N_3O_4S$, M_r 299.35

153

Thienamycin was found in the culture broth of *Streptomyces cattleya* by Merck Sharp & Dohme in 1976, as a very unstable substance. It has a unique carbapenem structure, like that of the olivanic acids found in *S. olivaceus* by Beecham Research Laboratories in 1979 [294]. Thienamycin shows excellent activity against a variety of pathogenic bacteria, including *Pseudomonas aeruginosa.* Its chemical stability has been improved by derivatization with the formimidoyl group, and its biological stability has been improved by combining it with cilastatin, an inhibitor of kidney dihydropeptidase. The combination drug imipenem – cilastatin is now under study to evaluate its clinical efficacy and safety.

Aztreonam [*78110-38-0*], (**154**), azthreonam, $C_{13}H_{17}N_5O_8S_2$, M_r 435.44.

154

Aztreonam was synthesized by the Squibb Institute for Medical Research in 1981 starting with L-threonine. The synthesis was based on findings about bacterial β-lactam compounds of a monocyclic nature [295]. The β-lactam compounds, called monobactams, were isolated from *Chromobacterium violaceum, Agrobacterium radiobacter,* etc. Such monocyclic β-lactams of bacterial origin had previously been found independently in 1981 by Takeda Chemicals Industries in the culture broths of *Pseudomonas acidophila* and *P. mesoacidophila* and named sulfazecin and isosulfazecin, respectively [82] (see page 16). Aztreonam was selected from among hundreds of derivatives as a candidate for clinical trials because of its unique antibacterial spectrum and strong activity. This antibiotic shows excellent activity against a variety of gram-negative aerobic bacteria but no activity against gram-positive bacteria or anaerobes. Its efficacy and safety are now being clinically evaluated.

Tetracycline [*60-54-8*], (**155**), $C_{22}H_{24}N_2O_8$, M_r 444.45.

155

Tetracycline was first obtained from chlortetracycline by reductive dehalogenation at Lederle Laboratories and Pfizer in 1953 [296]. It was also obtained either by fermentation of the chlortetracycline-producing organism, *Streptomyces aureofaciens,* under conditions of chlorine limitation, or by fermentation of a mutant of the organism lacking the chlorinating enzyme. Tetracycline is more stable than chlortetracycline in aqueous solution. Its antimicrobial activity is the same as that of chlortetracycline and oxytetracycline, but its serum concentration after oral administration is considerably higher and more enduring.

Chlortetracycline hydrochloride [*64-72-2*], (**156**), $C_{22}H_{23}ClN_2O_8 \cdot HCl$, M_r 515.35.

156

Chlortetracycline was found in the culture broth of *Streptomyces aureofaciens* by DUGGAR et al. of Lederle Laboratories in 1948 and named aureomycin [85]. It shows a wider range of antibiotic activity than the earlier antibiotics, penicillins, and streptomycins and as great as that of chloramphenicol. Its activity covers gram-positive and gram-negative bacteria as well as *Rickettsia* and *Chlamydiae.* Chlortetracycline has been replaced by other tetracyclines in clinical use and is used now used as a feed additive to promote the growth of livestock.

Demethylchlortetracycline [*127-33-3*], (**157**), demeclocycline, $C_{21}H_{21}ClN_2O_8$, M_r 464.86.

157

Demethylchlortetracycline was isolated from the culture broth of a mutant of *Streptomyces aureofaciens,* the chlortetracycline-producing strain, by Lederle Research Laboratories in 1957 [297]. It shows one and one-half to two times as much in vitro antimicrobial activity and in vivo protective effect as tetracycline. Its base and hydrochloride have been used orally and by topical application to treat infections caused by *Staphylococcus, Streptococcus, Rickettsia, Chlamydiae, Neisseria, Klebsiella, Proteus, Escherichia coli,* and *Haemophilus influenzae.*

Oxytetracycline [*6153-64-6*], (**158**), $C_{22}H_{24}N_2O_9 \cdot 2\,H_2O$, M_r 496.48.

158

Oxytetracycline was found in the culture broth of *Streptomyces rimosus* by Pfizer in 1950 and named terramycin [298]. It is closely related to chlortetracycline (aureomycin), and its structure was elucidated in 1952. Oxytetracycline has had wide clinical use as a substitute for chlortetracycline, even after the introduction of tetracycline. Oxytetracycline is administered orally, topically, and parenterally.

Methacycline [*914-00-1*], (**159**), metacycline, $C_{22}H_{22}N_2O_8$, M_r 442.43.

159

Methacycline was synthesized by Pfizer Research Laboratories in 1961 starting with oxytetracycline [299]. It shows two to fivefold greater in vitro antibacterial activity and in vivo protective activity than tetracycline. Methacycline has been given orally to treat infections by *Rickettsia, Chlamydiae, Staphyloccus, Streptococcus, Neisseria, Klebsiella, Proteus, Escherichia coli,* and *Haemophilus influenzae*.

Doxycycline [*17086-28-1*], (**160**), $C_{22}H_{24}N_2O_8 \cdot H_2O$, M_r 462.46.

160

Doxycycline was synthesized by Pfizer starting with either tetracycline or oxytetracycline in 1958 [300]. It shows about fourfold higher antibacterial activity than tetracycline against a variety of pathogens. Doxycycline shows higher oral absorption than tetracycline, and its concentration in tissue is higher and maintained longer. Hyclate is a preparation of doxycycline containing one mole of hydrochloric acid and one-half mole each of ethanol and water per mole of doxycycline.

Rolitetracycline [*751-97-3*], (**161**), $C_{27}H_{33}N_3O_8$, M_r 527.58.

161

Rolitetracycline was synthesized in 1958. Bristol-Myers Laboratories prepared it from tetracycline by introducing a pyrrolidinylmethyl moiety [301]. This antibiotic is very soluble in water and more stable than tetracycline under acidic conditions. Rolitetracycline is used by intravenous injection, and its nitrate is used by both intravenous and intramuscular injections for therapy of the same infections as those treated by tetracycline.

Minocycline [*10118-90-8*], (**162**), $C_{23}H_{27}N_3O_7$, M_r 457.49.

162

Minocycline was synthesized by American Cyanamid in 1966 in the course of studies on derivatives of 6-deoxytetracyclines [302]. It shows activity against tetracycline-resistant bacteria and higher activity than tetracycline against a variety of pathogens. Minocycline has a higher oral absorption than tetracycline, and its concentrations in several tissues are four to tenfold higher than that of tetracycline. It is widely used by oral administration, and it is also administered by drip infusion for serious infections.

Daunorubicin hydrochloride [*23541-50-6*], (**163**), $C_{27}H_{29}NO_{10} \cdot HCl$, M_r 563.99.

163

Daunorubicin was found independently by Farmitalia and Rhône Poulenc in 1963 in the mycelium of *Streptomyces peucetius* and the culture broth of *Streptomyces coeruleorubidus,* respectively [303]. It was the first anthracycline antibiotic clinically used for therapy of cancers, especially leukemia. Daunorubicin is used in combination with other anticancer drugs.

Doxorubicin [*23214-92-8*], (**164**), $C_{27}H_{29}NO_{11}$, M_r 543.53.

164

Doxorubicin was found in the culture broth of *Streptomyces peucetius* var. *cesius* by Farmitalia in 1967 in the course of studies of anthracycline antibiotics [304]. It shows stronger activity against a variety of tumors and leukemia than daunorubicin, and its clinical application in the therapy of cancer is wider than that of daunorubicin. Doxorubicin is sometimes called by its old generic name, adriamycin, especially in the medical field.

Aclarubicin [*57576-44-0*], (**165**), $C_{42}H_{53}NO_{15}$, M_r 811.89.

165

Aclarubicin was found in the culture broth of *Streptomyces galilaeus* MA144-M1 by Umezawa et al. of the Institute of Microbial Chemistry in 1975 [305]. It was produced along with structurally related compounds showing antileukemic activity and named aclacinomycin A. Sanraku-Ocean cooperated in isolating aclacinomycin A as a yellow crystalline powder and evaluated its strong antileukemic activity and low cardiac toxicity. Its generic name was changed to aclarubicin on the recommendation of the World Health Organization.

Kanamycin sulfate [*25389-94-0*], (**166**), $C_{18}H_{36}N_4O_{11} \cdot H_2SO_4$, M_r 582.59.

166

Kanamycin was found by UMEZAWA et al. in the culture broth of *Streptomyces kanamyceticus* in 1957 [306]. It is produced with other components, kanamycins B (bekanamycin) and C, which are also separated during the purification. The compound shows much lower toxicity than the earlier aminoglycosides, streptomycin and neomycin, and strong activity against a wide range of gram-positive and gram-negative bacteria, including *Mycobacterium.* Kanamycin has been used clinically for treatment of such serious infections as dysentery, salmonellosis, and tuberculosis.

Bekanamycin [*4696-76-8*], (**167**), kanamycin B, $C_{18}H_{37}N_5O_{10}$, M_r 483.52.

167

Bekanamycin, kanamycin B, was found in the culture broth of *Streptomyces kanamyceticus* by UMEZAWA et al. in 1957 [307]. It shows the same antibacterial spectrum as kanamycin but with stronger activity. The total synthesis of bekanamycin was completed by UMEZAWA et al. in 1968 and the knowledge gained from its synthesis was successfully applied to the synthesis of dibekacin.

Tobramycin [*32986-56-4*], (**168**), $C_{18}H_{37}N_5O_9$, M_r 467.52.

168

Tobramycin was found in 1967 by Eli Lilly Co. in the nebramycins complex that was produced in the culture broth of *Streptomyces tenebrarius* [308]. Structurally it is closely related to kanamycin, a naturally produced 3′-deoxy derivative of bekanamycin. The 3′-hydroxyl group was found to be the target of enzymatic phosphorylation by resistant bacteria. As expected, tobramycin shows strong activity against resistant bacteria, including *Pseudomonas aeruginosa,* having this phosphorylating enzyme.

Gentamicin sulfate [*1405-41-0*], (**169**), gentamicin.

Gentamicin C_1, $C_{21}H_{43}N_5O_7$, M_r 477.61.
Gentamicin C_2, $C_{20}H_{41}N_5O_7$, M_r 463.58.
Gentamicin C_{1a}, $C_{19}H_{39}N_5O_7$, M_r 449.55.

169

Gentamicin was found by Schering Plough Co. in the culture broths of *Micromonospora purpurea* and *M. echinospora* in 1963 [309]. It is a mixture of at least 16 structurally related components. The major components used in clinical preparations are gentamicins C_{1a}, C_1, and C_2. Gentamicin shows high activity against a variety of gram-positive and gram-negative bacteria, including *Pseudomonas aeruginosa, Proteus,* and *Serratia.* It has been widely used for the clinical treatment of serious infections. Gentamicin is used alone or in combination with β-lactam antibiotics and is being replaced gradually by the newer, less toxic aminoglycosides.

Dibekacin [*34493-98-6*], (**170**), $C_{18}H_{37}N_5O_8$, M_r 451.52.

170

Dibekacin was synthesized in 1967 by UMEZAWA et al. by the removal of the 3′- and 4′-hydroxyl groups of kanamycin B [310]. Studies by the same workers on the mechanisms of bacterial resistance to kanamycin-group antibiotics preceded the discovery. Dibekacin shows excellent activity, as expected, against a variety of bacteria, including kanamycin-resistant strains. It shows higher activity than kanamycin against *Pseudomonas aeruginosa, Proteus,* and other pathogens.

Amikacin [*37517-28-5*], (**171**), $C_{22}H_{43}N_5O_{13}$, M_r 585.61.

171

Amikacin was synthesized by KAWAGUCHI et al. of the Bristol-Banyu Research Institute in 1970 starting with kanamycin and the acyl moiety of butirosin [311]. Its design is based on knowledge of the mechanisms of bacterial resistance to kanamycin and related compounds in which the 3′-hydroxyl group of the antibiotic is phosphorylated enzymatically. The acyl moiety in butirosin prevents this enzymatic inactivation.

Micronomicin [*52093-21-7*], (**172**), $C_{20}H_{41}N_5O_7$, M_r 463.58.

172

Micronomicin, formerly called sagamicin, was found in the culture broth of *Micromonospora sagamiensis* var. *nonreducans* by Kyowa Hakko Kogyo Company and Abbott Laboratories in 1974 [312]. The compound is identical with one of the minor components contained in gentamicin, gentamicin C_{2b}, but it is produced as a single component. Its amino group at the 6′-position is methylated and is not subject to the enzymatic acetylation caused by resistant bacteria, including *Pseudomonas aeruginosa.* Micronomicin is less toxic than gentamicin to the renal and aural systems.

Ribostamycin [*25546-65-0*], (**173**), $C_{17}H_{34}N_4O_{10}$, M_r 454.48.

173

Ribostamycin was found in the culture broth of *Streptomyces ribosidificus* by Meiji Seika Kaisha in 1970 in the course of screening aminoglycoside antibiotics [313]. It is structurally related to neomycin but lacks the diaminoidose (glucose) moiety substituted on the ribose moiety. Ribostamycin is much less toxic than neomycin and shows strong activity against a variety of gram-positive and gram-negative bacteria, except *Pseudomonas aeruginosa.* It is used parenterally for therapy of urinary tract, respiratory tract, surgical, and other infections.

Neomycin sulfate [*1405-10-3*], (**174**), fradiomycin, $C_{23}H_{46}O_{13}N_6$, M_r 614.66.

174

Neomycin was found independently in 1949, by UMEZAWA et al. and WAKSMAN et al. in the culture broth of *Streptomyces fradiae* [314]. It consists of two closely related components, B and C, and shows strong activity against a wide range of gram-positive and gram-negative bacteria, including *Serratia* and *Pseudomonas aeruginosa.* Because of its renal and ototoxicity, it is given orally or by topical application. Because it is not absorbed orally, as are other aminoglycoside antibiotics, it is used orally only for the purpose of suppressing intestinal flora, i.e., in treating dysentery, salmonellosis, and diarrhea in the pediatric field. Neomycin also has been used topically in the treatment of bacterial infections of the eye and skin.

Paromomycin sulfate [*1263-89-4*], (**175**), $C_{23}H_{45}N_5O_{14} \cdot xH_2SO_4$, M_r 615.64 (base).

175

Paromomycin was found in the culture broth of *Streptomyces rimosus* forma *paromomycinus* by Parke Davis & Co. in 1959 [315]. In the same year it was found in the culture broth of *S. Crestomyceticus* by Farmitalia and named amminosidin. Paromomycin is related structurally to neomycin, but it has a hydroxyl group at the 6′ position, whereas neomycin has an amino group. Its antibacterial activity is weaker than that of neomycin, but its toxicity is much less. Paromomycin is used by intramuscular injection for therapy of respiratory, urinary, and surgical infections and by oral administration to treat dysentery and salmonellosis.

Streptomycin sulfate [*3810-74-0*], (**176**), $C_{42}H_{84}N_{14}O_{36}S_3$, M_r 1457.40.

176

Streptomycin was found in the culture broth of *Streptomyces griseus* by S. A. WAKSMAN of Rutgers University in 1944; it was the second antibiotic introduced clinically (after penicillin) [316]. This drug is a water soluble, basic substance having an aminoglycoside structure and showing strong activity against a wide range of gram-positive and gram-negative bacteria including *Mycobacterium.* Streptomycin is the first choice among antituberculotic antibiotics and has been used for the therapy of *Spirochaeta* and *Treponema* infections.

Dihydrostreptomycin [*128-46-1*], (**177**), $C_{21}H_{41}N_7O_{12}$, M_r 583.60.

177

Dihydrostreptomycin was first synthesized by Parke Davis Co. in 1946 by the reduction of streptomycin [317]. Naturally occurring dihydrostreptomycin was found in the culture broth of *Streptomyces humidus* by Takeda Chemicals Industries in 1957. Its hydrochloride or sulfate is more easily crystallized and more stable under alkaline conditions than streptomycin. Dihydrostreptomycin has been used for therapy of tuberculosis, but because it has a higher ototoxicity than streptomycin its use is now restricted to animal therapy.

Destomycin A [*14918-35-5*], (**178**), $C_{20}H_{37}N_3O_{13}$, M_r 527.53.

178

Destomycin A was found in the culture broth of *Streptomyces rimofaciens* by Meiji Seika Kaisha in 1965 in the course of screening for water-soluble and basic antibiotics, such as aminoglycosides [318]. It shows activity against a variety of gram-positive and gram-negative bacteria as well as fungi and, more interestingly, against helminths. Destomycin A has been used to treat helminth infections in swine and poultry.

Hygromycin B [*31282-04-9*], (**179**), $C_{20}H_{37}N_3O_{13}$, M_r 527.53.

179

Hygromycin B was found in the culture broth of *Streptomyces hygroscopicus* by Lilly Research Laboratories in 1953, as a mixture with hygromycin A [319]. It showed activity against a variety of gram-positive and gram-negative bacteria as well as fungi. Hygromycin B has been used for therapy of helminthic infections in swine and poultry.

Apramycin [*41194-16-5*], (**180**), $C_{21}H_{41}N_5O_{11}$, M_r 539.59.

180

Apramycin was found in the culture broth of *Streptomyces tenebrarius* by Eli Lilly in 1967 as one of the eight components of the nebramycin complex [320]. Apramycin is used in feed additives.

Sisomicin [*32385-11-8*], (**181**), $C_{19}H_{37}N_5O_7$, M_r 447.54.

181

Sisomicin was found in the culture broth of *Micromonospora inyoensis* by Schering-Plough Co. in 1970, following the discovery of gentam-

icin by the same research group [321]. The structure and activity of sisomicin are very similar to those of gentamicin C_{1a}, the major component of the gentamicin complex. Sisomicin shows stronger bacterial activity and lower renal and ototoxicity than gentamicin C_{1a}.

Netilmicin sulfate [*56391-57-2*], (**182**), $(C_{21}H_{41}N_5O_7)_2 \cdot 5\,H_2SO_4$, M_r 1441.57.

182

Netilmicin was synthesized by Schering-Plough Co. in 1976 [322]. The ethyl moiety was introduced at the 1-amino group of sisomicin. Its design was based on an understanding of the biochemical mechanisms of bacterial resistance to the gentamicin – sisomicin antibiotic group. The modification at the 1-amino group is known to prevent adenylation at the 2″-hydroxyl group and acetylation at the 3-amino group, and to deter acetylation at the 6′-amino residue. Netilmicin shows almost the same activity against a variety of gram-positive and gram-negative bacteria as sisomicin and strong activity against gentamicin – sisomicin-resistant bacteria. It is now under study for evaluation of its clinical efficacy and safety.

Spectinomycin hydrochloride [*22189-32-8*], (**183**), $C_{14}H_{24}N_2O_7 \cdot 2\,HCl \cdot 5\,H_2O$, M_r 495.36.

183

Spectinomycin was found in the culture broth of *Streptomyces spectabilis* by Upjohn Co. in 1961 [323]. This antibiotic was intended for use in treating various infections, as are the other aminoglycoside antibiotics, but its activity is insufficient for clinical efficacy except against gonorrhea. Spectinomycin does not develop crossresistance with any other antibiotic and shows low toxicity; it is used by deep intramuscular injection for "single-session," bolus-injection therapy of gonorrhea.

Astromicin sulfate [*72275-67-3*], (**184**), fortimicin A, $C_{17}H_{35}N_5O_6 \cdot 2\,H_2SO_4$, M_r 601.65.

184

Astromicin was found in the culture broth of *Micromonospora olivoasterospora* by Nara et al. of Kyowa Hakko Kogyo Co. in 1976 [324]. It has a unique conformation with an acylated diamino inositol moiety different from other aminoglycoside antibiotics. Astromicin is produced with one major byproduct, fortimicin B, and several minor components.

Validamycin [*37248-47-8*], (**185**), validamycin A, $C_{20}H_{35}NO_{13}$, M_r 497.50.

Validamycin A
185

Validamycin was found in the culture broth of *Streptomyces hygroscopicus* var. *limoneus* by Takeda Chemicals Industries in 1971 in the course of screening for substances active against sheath blight in the rice plant [325]. It consists of five components. The major component, validamycin A, was found to be the major contributor to the activity. Validamycin is active against a variety of phytopathogenic fungi, especially *Pel-*

licularia sasakii, and it has been used to protect rice plants against sheath blight.

Kasugamycin [*6980-18-3*], (**186**), $C_{14}H_{25}O_9N_3$, M_r 379.37.

186

Kasugamycin was found in the culture broth of *Streptomyces kasugaensis* by UMEZAWA et al. in 1965 [326]. It has an aminocyclitol structure and shows strong activity against phytopathogenic fungi, especially *Pericularia oryzae,* the pathogen causing rice blast. This drug also shows activity against *Pseudomonas,* and its toxicity is very low; no mice died following intravenous injection of doses as high as two grams per kilogram. Kasugamycin has been used to protect rice plants against rice blast and for animal infections.

Polyoxin [*11113-80-7*], (**187**), polyoxin A [*19396-03-3*], $C_{23}H_{32}N_6O_{14}$, M_r 616.54, polyoxin B, [*19396-06-6*], $C_{17}H_{25}N_5O_{13}$, M_r 507.41.

187

Polyoxin was found in the culture broth of *Streptomyces cacaoi* var. *asoensis* by SUZUKI et al. in 1965 [145–147]. It consists of several closely related components, A through O, and shows activity against phytopathogenic fungi by inhibition of cell-wall chitin synthesis. Polyoxin has been used in agriculture against fungal infections, especially *Alternaria* leaf spot in vegetables and fruits.

Blasticidin S [*2079-00-7*], (**34**), $C_{17}H_{26}N_8O_5$, M_r 422.45 (for structure, see page 28).

Blasticidin S was found in the culture broth of *Streptomyces griseochromogenes* by YONEHARA et al. of the University of Tokyo in 1958 [157]. It has a nucleoside-analogue structure and shows strong activity against phytopathogenic fungi, especially *Pericularia oryzae,* the pathogen causing rice blast. Blasticidin S has been used to protect rice plants.

Erythromycin [*114-07-8*], (**188**), $C_{37}H_{67}NO_{13}$, M_r 733.95.

Erythromycin, the first of the macrolide antibiotics, was found in the culture broth of *Streptomyces erythreus* by Eli Lilly Co. in 1952 [327].

188

Its chemical structure and synthesis have been studied extensively by the WOODWARD group at Harvard University. Erythromycin shows activity against gram-positive bacteria and gram-negative cocci as well as *Mycoplasma* and *Leptospira.* Oral administration of its base and esters is used widely in clinics to treat respiratory tract and other infections. An ester, lactobionate, is used by drip infusion for serious infections (see next two paragraphs).

Erythromycin estolate [*3521-62-8*], (**189**), erythromycin 2′-propionate dodecyl sulfate (salt), $C_{40}H_{71}NO_{14} \cdot C_{12}H_{26}O_4S$, M_r 1056.41.

189

Erythromycin estolate was synthesized by the Lilly Research Laboratories in 1959 [328]. It shows a higher and longer lasting serum level than erythromycin and the other esters, ethylsuccinate and stearate, when administered orally. This antibiotic is stable against gastric acids, and after oral absorption it is hydrolyzed gradually into erythromycin. Long-term usage of erythromycin estolate is toxic to the liver. Erythromycin ethylsuccinate [*41342-53-4*], ($C_{43}H_{75}NO_{16}$, M_r 862.07) and erythromycin stearate [*643-22-1*] ($C_{37}H_{67}NO_{13} \cdot C_{18}H_{36}O_2$, M_r 1018.43) also have been used orally, and erythromycin lactobionate [*3847-29-8*] ($C_{37}H_{67}NO_{13} \cdot C_{12}H_{22}NO_{12}$, M_r 1092.25) has been used by intravenous administration and opthalmic topical application.

Oleandomycin phosphate [*7060-74-4*], (**190**), $C_{35}H_{61}NO_{12} \cdot H_3PO_4$, M_r 785.87.

190

Oleandomycin is a macrolide antibiotic with a 14-membered lactone constituent. It was found in the culture broth of *Streptomyces antibioticus* by Pfizer Research Laboratories in 1954 [329]. Oleandomycin shows almost the same antimicrobial spectrum and activity as the other macrolide antibiotics. Its serum concentration is low, but its tissue concentration is high enough to provide a therapeutic effect. Oleandomycin phosphate is used orally or intravenously to treat pyoderma, sepsis, meningitis, surgical and abdominal infections, respiratory tract and urinary tract infections, and other infections caused by *Staphylococci, Streptococci, Corynebacterium, Neisseria,* and *Mycoplasma.* Oleandomycin is also used as a feed additive and therapeutic agent for animals.

Triacetyloleandomycin [*2751-09-9*], (**191**), troleandomycin, $C_{41}H_{67}NO_{15}$, M_r 813.99.

191

Triacetyloleandomycin was synthesized by Pfizer Research Laboratories in 1958 [330]. It shows a higher and longer-lasting serum level than oleandomycin when administered orally. Triacetyloleandomycin behaves as oleandomycin in vivo, following its hydrolysis by intestinal esterase. However, considerable amounts of the intermediates, the monoacetates and diacetates, are detected in the serum and urine. Prolonged use of triacetyloleandomycin causes damage to the liver as does erythromycin estolate.

Kitasamycin [*1392-21-8*], (**192**),

Leucomycin A_1: R^1 = H, R^2 = $COCH_2CH(CH_3)_2$
Leucomycin A_3: R^1 = $COCH_3$, R^2 = $COCH_2CH(CH_3)_2$
Leucomycin A_4: R^1 = $COCH_3$, R^2 = $COCH_2CH_2CH_3$
Leucomycin A_5: R^1 = H, R^2 = $COCH_2CH_2CH_3$
Leucomycin A_6: R^1 = $COCH_3$, R^2 = $COCH_2CH_3$
Leucomycin A_7: R^1 = H, R^2 = $COCH_2CH_3$

192

Kitasamycin, formerly called leucomycin, was found in the culture broth of *Streptoverticillium kitasatoensis* by Hata et al. of the Kitasato Institute, Japan, in 1953 [166]. This was the first macrolide antibiotic with a 16-membered lactone constituent. Kitasamycin is a complex of eight leucomycin A components and is used in its base and ester forms to treat gram-positive bacterial and gram-negative coccal infections, as well as infections of *Mycoplasma, Spirochaeta,* and *Treponema* by injection or by oral topical administration.

Josamycin [*56689-45-3*], (**193**), $C_{42}H_{69}NO_{15}$, M_r 828.02.

193

Josamycin was found in the culture broth of *Streptomyces narboensis* var. *josamyceticus* by Yamanouchi Pharmaceutical Co. and the Institute of Microbial Chemistry in 1964 [331]. It was the first macrolide antibiotic with a 16-membered lactone constituent to be prepared as a single compound. Its lactone structure was first thought to be 17-membered, but later this idea was revised and its identity with leucomycin A_3, a component of kitasamycin, was confirmed. Clinically, josamycin is given to children in the form of a base or propionate ester to avoid its bitter taste.

Spiramycin [*8025-81-8*], (**194**).

194

Spiramycin was found in the culture broth of *Streptomyces ambofaciens* by Rhône Poulenc in 1954 [168] and its acetate was synthesized by Kyowa Hakko Kogyo Co. in 1965. This antibiotic consists of three closely related macrolide components, I, II, and III, whose ratio is 2 : 1 : 1. Spiramycin shows almost the same antimicrobial spectrum and activity as the other macrolides, but its acetate, acetylspiramycin, has much better pharmacokinetic properties and activity in vivo.

Tylosin [*1401-69-0*], (**195**), $C_{46}H_{77}NO_{17}$, M_r 916.12.

195

Tylosin was found in the culture broth of *Streptomyces fradiae* by Lilly Research Laboratories in 1959 [179–181]. It shows the same antimicrobial spectrum as the other macrolide antibiotics, and its activity against *Mycoplasma* is the widest and highest of any member of its group. Against gram-positive bacteria it is slightly weaker than erythromycin. Tylosin shows a very high and long-term tissue concentration when administered subcutaneously. It is used by injection or oral administration to treat *Mycoplasma* and gram-positive bacterial infections in poultry, swine, and other livestock.

Ivermectin [*70288-86-7*], (**196**), component B_{1a} [*70161-11-4*], component B_{1b} [*70209-81-3*].

196

Ivermectin was synthesized starting with avermectin, which was found by Merck Sharp & Dohme in the culture broth of *Streptomyces*

avermitilis in 1977 [332]. Unlike other antibiotics, its activity is strictly against insects, mites, and animal parasites. Ivermectin has been used against pests, mites, and other parasites in domestic animals and livestock.

Midecamycin [*35457-80-8*], (**197**), $C_{41}H_{67}NO_{15}$, M_r 813.99.

197

Midecamycin, a macrolide antibiotic having a 16-membered lactone ring, was found in the culture broth of *Streptomyces mycarofaciens* by Meiji Seika Kaisha in 1971 [333]. Under specific culture conditions, it is produced by the organism as a single component. Midecamycin shows almost the same antimicrobial spectrum and activity as kitasamycin. Although its serum and urine concentrations are low, it distributes in tissues at high concentration following oral administration.

Rifampicin [*13292-46-1*], (**198**), rifampin, $C_{43}H_{58}N_4O_{12}$, M_r 822.96.

198

Rifampicin was synthesized from rifamycin O obtained from a culture of *Nocardia mediterranei* by Lepetit and Ciba Geigy in 1967 [334]. It shows strong activity against gram-positive bacteria and gram-negative cocci, including *Mycobacterium*, and against viruses. Its clinical application has been restricted to the therapy of tuberculosis caused by streptomycin-resistant tuberculotic bacteria, but recently its usefulness against infections by *Legionella* has been considered.

Bleomycin sulfate [*9041-93-4*], (**199**), variable composition.

Bleomycin was found by UMEZAWA et al. in the culture broth of *Streptomyces verticillus* B80-Z2 in 1965 as a mixture of 13 closely related components [193]. It is produced as a complex with copper (II) ion showing a blue color. Removal of the copper ion with 8-hydroxyquinoline gives a slightly yellowish powder that has the same anticancer activity as the complex but is less toxic. The major component of bleomycin sulfate is bleomycin A_2, which shows strong activity and low toxicity. It is effective against skin, head, neck, lung, and other cancers and malignant lymphoma.

(Main component: Bleomycin A_2, in which R is $(CH_3)_2S^+CH_2CH_2CH_2-$)

199

Peplomycin sulfate [*70384-29-1*], (**200**), pepleomycin, $C_{61}H_{88}N_{18}O_{21}S_2 \cdot H_2SO_4$, M_r 1571.70.

Peplomycin was derived biosynthetically from *Streptomyces verticillus,* the bleomycin-producing organism, in the course of efforts to obtain bleomycin derivatives with high activity and low toxicity. This antibiotic was found by Nippon Kayaku Co. and the Institute of Microbial Chemistry, Japan, in 1974 [335]. Its anticancer effects appear earlier than those of bleomycin; consequently, the period of therapy is shortened. Peplomycin is also active against

200

metastatic cancer of the lymph nodes and shows less pneumotoxicity than bleomycin.

Gramicidin S [*113-73-5*], (**201**), $C_{60}H_{92}N_{12}O_{10}$, M_r 1141.48.

201

Gramicidin S was found in the culture broth of *Bacillus brevis* by GAUSE of the USSR Academy of Medical Sciences in 1944 [199]. It was later found by OTANI of Osaka University in the cells of the *Nagano* strain of the same species. The antibiotic is a basic peptide showing strong activity against gram-positive bacteria and considerable activity against gram-negative cocci and *Mycobacterium.* Gramicidin S is rather toxic but is not absorbed orally; it is used topically as an ointment or as eye or ear drops in combination with other antibacterial drugs.

Polymyxin B [*1404-26-8*], (**202**).

Polymyxin B was isolated by Wellcome Research Laboratories, in 1949, from the mixture of polymyxins A, B, C, and D produced by *Bacillus polymyxa* [336]. It was later separated into the major component, B_1, and the minor component, B_2. Polymyxin B is a basic polypeptide and shows strong activity against gram-negative bacteria, but its activity against gram-positive bacteria, *Mycobacterium,* and fungi is weak. Because of its toxicity, it is used carefully by intramuscular injection for resistant *Pseudomonas aeruginosa* infections, e.g., sepsis. Polymyxin B is used orally to sterilize the gut in leukemic patients, intraspinally for meningitis, or topically.

Dab = α, γ-diaminobutyric acid

Polymyxin B_1, [*4135-11-9*], $C_{56}H_{98}N_{16}O_{13}$: M_r *1203.50*, R = (+)-6-methyloctanoyl; X = phenylalanine; Y = leucine; Z = L-Dab

Polymyxin B_2, [*34503-87-2*], $C_{55}H_{96}N_{16}O_{13}$: M_r *1189.48*, R = 6-methylheptanoyl; X = phenylalanine; Y = leucine; Z = L-Dab

202

Bacitracin [*1405-87-4*], bacitracin A (the major component) [*22601-59-8*] (**203**), $C_{66}H_{103}N_{17}O_{16}S$, M_r 1422.73.

203

Bacitracin was found as a polypeptide complex in the culture broth of *Bacillus subtilis* and *B. licheniformis* by JOHNSON of Columbia University in 1945 [337]. It was first used as a mixture of at least nine bacitracin components. The structure of bacitracin A was determined in 1966 by RESSLER et al. [203].

Colistin sulfate [*1264-72-8*], (**204**), $C_{45}H_{85}O_{10}N_{13} \cdot 2.5\,H_2SO_4$, M_r 1213.45.

Colistin was found in the culture broth of *Bacillus polymyxa* var. *colistinus* by Kayaku Antibiotics Research in 1950 [338]. It is closely related to polymyxin and shows strong activity against gram-negative bacteria, including *Pseudomonas aeruginosa.* Colistin and its methanesulfonic acid derivative have been used to treat urinary tract infections caused by *Escherichia coli* and *P. aeruginosa.* They have also been used parenterally to treat dysentery and abdominal infections and topically for ophthalmic and otorhinolaryngological infections.

Colistinmethanesulfonate sodium (**205**) [*8068-28-8*], colistimethate sodium, $C_{58}H_{107}N_{16}Na_5O_{28}S_5$ (colistin A component), M_r 1749.84; [*21362-08-3*] $C_{57}H_{103}N_{16}Na_5O_{28}S_5$ (colistin B component), M_r 1735.82.

Colistinmethansulfonate was synthesized by Kayaku Antibiotics Research Co. in 1955 [339]. It is much less toxic than colistin and has been used intramuscularly and orally to treat infections caused by *Pseudomonas aeruginosa, Escherichia coli, Klebsiella pneumoniae, Enterobacter,* and *Shigella.*

Dab is L-α, γ-diaminobutyric acid; R is 5-methylheptyl in colistin A and 5-methylhexyl in colistin B

204

Dab is L-α, γ-diaminobutyric acid; R is $CH_3CH_2CH(CH_2)_4$ in the colistin A component and $CH_3CH(CH_2)_4$ in the colistin B component; R' is CH_2SO_3Na

205

Enramycin A: R = CH_3
Enramycin B: R = C_2H_5
K_1: α-Amino-4-hydroxyphenylacetic acid
K_2: α-Amino-3,5-dichloro-4-hydroxyphenylacetic acid
Y_1: α(*S*)-Amino-β-4(*R*)-(2-iminoimidazolidinyl)propionic acid
Y_2: α(*R*)-Amino-β-4(*R*)-(2-iminoimidazolidinyl)propionic acid

206

Enramycin [*11115-82-5*], (**206**), enduracidin, A: $C_{107}H_{138}N_{25}O_{31}Cl_2$, M_r 2355.35; B: $C_{108}H_{140}N_{26}O_{31}Cl_2$, M_r 2369.38.

Enramycin, formerly called enduracidin, was found in the culture broth of *Streptomyces fungicidicus* by Takeda Chemicals Industries in 1967 [340]. This antibiotic shows strong activity against gram-positive bacteria but not against gram-negative bacteria. It is not subject to any of the mechanisms of resistance against other antibiotics and shows activity against otherwise resistant strains. Enramycin was evaluated for human therapy, but it is now used as a feed additive for growth promotion in poultry.

Mikamycin [*11006-76-1*], mikamycin B [*3131-03-1*] (**207**), $C_{45}H_{54}N_8O_{10}$, M_r 866.98.

Mikamycin B

207

Mikamycin was found in the culture broth of *Streptomyces mitakaensis* by UMEZAWA et al. of the University of Tokyo in 1956 [341]. It is a mixture of two components, A and B, showing synergistic effects on each other. Staphylomycin, which was found by DE SOMER of Leuven University in 1955, is a closely related compound. Mikamycin shows strong activity against gram-positive bacteria, including strains resistant to other antibiotics. It has been used topically to treat *Staphylococcus* or *Streptococcus* infections of the skin, including burns.

Virginiamycin [*11006-76-1*], (**208**),

Virginiamycin, formerly called staphylomycin, was found in the culture broth of *Streptomyces virginiae* by DE SOMER et al. of Leuven University in 1955 [342]. The commercial product contains about 75 % of the fraction M_1 and 5 % of the fraction S. The structure of the minor component, M_2, has not yet been elucidated. Virginiamycin has very low toxicity and is not absorbed from the intestine when administered orally. It shows activity against gram-positive bacteria, and it has been used as a feed additive for growth promotion in swine, cattle, and other livestock.

Factor S, $C_{42}H_{47}N_7O_{10}$, M_r 809.88

208

Capreomycin sulfate [*1405-37-4*], (**209**),

Capreomycin was found as an antituberculotic antibiotic by HERR et al. of Eli Lilly & Co. in the culture broth of *Streptomyces capreolus* NRRL2773 in 1962 [343]. It shows no cross-resistance with streptomycin and is used against tuberculosis caused by streptomycin-resistant *Mycobacterium* or for patients with adverse side effects caused by streptomycin (see next page).

Viomycin [*32988-50-4*], (**210**), $C_{25}H_{43}N_{13}O_{10}$, M_r 685.70.

210

Viomycin was found independently in 1951, in the culture broth of *Streptomyces puniceus*

Capreomycin I A : R = OH; $C_{25}H_{44}N_{14}O_8 \cdot 2\ H_2SO_4$, M_r 864.87
Capreomycin I B : R = H; $C_{25}H_{44}N_{14}O_7 \cdot 2\ H_2SO_4$, M_r 848.87

209

by Pfizer Research Laboratories and in that of *S. floridae* by Parke Davis Co. [344]. It shows strong activity against *Mycobacterium* species and moderate activity against gram-positive and gram-negative bacteria. Viomycin has been used by intramuscular administration to treat tuberculosis, but because of its ototoxicity and renal toxicity it is being replaced by more active and less toxic drugs, such as enviomycin and other antituberculotic antibiotics.

Enviomycin [*33103-22-9*], (**211**), tuberactinomycin N, $C_{25}H_{43}N_{13}O_{10}$, M_r 685.70.

211

Enviomycin was found in the culture broth of *Streptomyces griseoverticillatus* var. *tuberacticus* by Toyo Jozo Co. in 1966 as a mixture of tuberactinomycins N and O [345]. It is a water-soluble, basic peptide closely related to viomycin and showing selective activity against *Mycobacterium* species about twice as strong as that of viomycin. Enviomycin, in combination with other antituberculotic drugs, is used to treat tuberculosis caused by streptomycin-resistant *Mycobacterium.*

Vancomycin [*1404-90-6*], (**212**), $C_{66}H_{75}Cl_2N_9O_{24}$, M_r 1449.29.

212

Vancomycin was found by Lilly Research Laboratories in 1956 in the culture broth of *Streptomyces orientalis* [346]. It is a large, molecular glycopeptide showing bactericidal activity against gram-positive bacteria and anaerobes. It is used to treat resistant infections of *Staphylococcus,* to sterilize the gut in the perioperation of bone-marrow transplantation, and in leukemic patients. Recently its efficacy has been demonstrated against pseudomembrane colitis, which is caused by *Clostridium difficile*.

Actinomycin D [*50-76-0*], (**213**), dactinomycin, $C_{62}H_{86}N_{12}O_{16}$, M_r 1255.45.

213

215

Actinomycins (mixtures of A, B, C, and other components) were first found by WAKSMAN et al. of Rutgers University in 1940 in the culture broth of *Streptomyces antibioticus* [347]. The mixture of the C components has been used as cactinomycin for anticancer therapy. Actinomycin D was found by the same group in 1954, obtained as a single component from *S. parvullus*. Its strong activity against Wilm's tumor and other cancers has been evaluated. Dactinomycin is the name recommended by INN and used in the United States.

Neocarzinostatin [*9014-02-2*], zinostatin.

Ala – Ala – Pro – Thr – Ala – Thr – Val – Thr – Pro – Ser – Ser – Gly – Leu – Ser – Asp – Gly – Thr – Val – Val – Lys – Val – Ala – Gly – Ala – Gly – Leu – Gln – Ala – Gly – Thr – Ala – Tyr – Asp – Val – Gly – Gln – Cys – Ala – Ser – Val – Asn – Thr – Gly – Val – Leu – Trp – Asn – Ser – Val – Thr – Ala – Ala – Gly – Ser – Ala – Cys – Asx – Pro – Ala – Asn – Phe – Ser – Leu – Thr – Val – Arg – Arg – Ser – Phe – Glu – Gly – Phe – Leu – Phe – Asp – Gly – Thr – Arg – Trp – Gly – Thr – Val – Asx – Cys – Thr – Thr – Ala – Ala – Cys – Gln – Val – Gly – Leu – Ser – Asp – Ala – Ala – Gly – Asp – Gly – Glu – Pro – Gly – Val – Ala – Ile – Ser – Phe – Asn

Neocarzinostatin was found in the culture broth of *Streptomyces carzinostaticus* by ISHIDA et al. of Tohoku University in 1957 [348]. It showed strong cytotoxicity against sarcoma 180 ascites, tumor cells, and leukemia SN-36. Neocarzinostatin was found to be an acidic peptide of M_r 10700, consisting of 109 amino acid residues. Recently the principal agent of anticancer and antibacterial activity in neocarzinostatin was found to be a small molecular chromophore with the peptide component playing a role by stabilizing the chromophore in vivo. Neocarzinostatin is used to treat leukemia and gastric and pancreatic cancer.

Bestatin [*58970-76-6*], (**214**), $C_{16}H_{24}N_2O_4$, M_r 308.38.

214

Bestatin was found in the culture broth of *Streptomyces olivoreticuli* in 1976 by UMEZAWA et al. in the course of screening specific enzyme inhibitors of microbial origin [349]. It shows inhibitory activity against specific exopeptidases, e.g., aminopeptidase B and leucine aminopeptidase. However, it does not act against aminopeptidase A, carboxypeptidases A and B, or endopeptidases. Bestatin acts as a bioresponse modifier and shows antitumor activity via stimulation of immuno response in the host. In combination with cytotoxic anticancer drugs, it is now under clinical evaluation for use in cancer therapy.

Pepstatin [*26305-03-3*], (**215**), $C_{34}H_{63}N_5O_9$, M_r 685.91.

Pepstatin was found in the culture broth of *Streptomyces testaceus* by UMEZAWA of the Institute of Microbial Chemistry in 1970 in the course of screening for specific enzyme inhibitors [350]. It shows strong inhibitory activity against several proteases, such as pepsin, cathepsin D, and renin, but not against trypsin, chymotrypsin, papain, etc. Its potential use against ulcers in humans and animals has been studied.

Monensin [*17090-79-8*], (**216**), $C_{36}H_{62}O_{11}$, M_r 670.89.

216

Monensin was found in the mycelium of *Streptomyces cinnamonensis* by Eli Lilly & Co. in 1967 in the course of screening for anticoccidial and growth-promoting substances for cattle, swine, and chickens [351]. It shows antiprotozoal, antibacterial, and antifungal activities, as well as anticoccidial activity. Monensin is widely used to treat such infections and as a feed additive to promote the growth of livestock.

Lasalocid [*25999-31-9*], (**217**), $C_{34}H_{54}O_8$, M_r 590.80.

217

Lasalocid is one of the polyether ionophore antibiotics and was found in the culture broth of *Streptomyces lasaliensis* by Hoffmann-La Roche in 1951 [352]. It shows activity against gram-positive bacteria, including *Mycobacterium* and *Streptomyces*, and also against anaerobic bacteria, but it has no activity against gram-negative bacteria or fungi. Lasalocid also shows strong anticoccidial activity, and it stimulates propionic acid formation in the rumen. It is used for prophylaxis and for therapy of coccidial infections in poultry and as a feed additive for growth promotion in cattle.

Salinomycin [*53003-10-4*], (**218**), $C_{42}H_{70}O_{11}$, M_r 751.02.

218

Salinomycin was found in the culture mycelium of *Streptomyces albus* by OTAKE et al. of the University of Tokyo in 1973 [353]. Like other polyether ionophore antibiotics, it shows activity against gram-positive bacteria, fungi, and *Coccidium*. Salinomycin has been used as a feed additive to protect poultry against coccidial infections.

Amphotericin B [*1397-89-3*], (**219**), $C_{47}H_{73}NO_{17}$, M_r 924.10.

219

Amphotericin B was found in the mycelium of *Streptomyces nodosus* M-4575 by GOLD et al. of the Squibb Institute of Medical Research in 1956 [354]. It is produced with another polyene macrolide antibiotic, amphotericin A, and separated by solvent extraction. Amphotericin B shows strong antimycotic activity against a variety of fungi and pathogenic yeasts (*Candida*) and is used by injection and as a vaginal suppository.

Nystatin [*1400-61-9*], (**220**).

Nystatin A_1 [*34786-70-4*], $C_{47}H_{75}NO_{17}$, M_r 926.12.

220

Nystatin was found in the mycelium of *Streptomyces noursei* in 1950 [355] and produced on an industrial scale by Squibb & Sons Co. in 1954. This antibiotic was used orally and topically as the first clinically applied polyene macrolide with antifungal properties. Nystatin shows activity against *Candida* and filamentous fungi and is used to treat *Candida* infections of the mouth, digestive organs, and vagina. The application of nystatin in combination with gentamicin and vancomycin to sterilize the gut in perioperation of bone-marrow transplantation has been developed recently.

Natamycin [*7681-93-8*], (**221**), pimaricin, $C_{33}H_{47}NO_{13}$, M_r 665.74.

221

Natamycin was found in the culture mycelium of *Streptomyces natalensis* by Royal

Antibiotic:	R^1	R^2	R^3	R^4	X^1	X^2	X^3	X^4	X^5
Trichomycin B:	H	H	COOH	H	H, OH	O	H, H	O	H, OH
Levorin A_2 (candicidin D):	H	CH_3	COOH	H	H, OH	O	H, H	O	H, OH
Hamycin (67-121 B):	H	H	COOH	H	H, OH	H, OH	H, OH	H, OH	H, OH

222

Dutch Yeast & Fermentation Industries and in that of *S. gilvosporeus* by American Cyanamid, independently, in 1957 [356]. It has a tetraene structure, and like other polyene macrolide antibiotics, it shows activity against pathogenic fungi. Natamycin has been used as a vaginal suppository for therapy of *Candida* infections.

Trichomycin [*1394-02-1*], (**222**), hachimycin.

Trichomycin (hachimycin in the INN) was found in the mycelium of *Streptomyces hachijoensis* by HOSOYA et al. of the University of Tokyo in 1952 [357]. It has a heptaene structure and once was considered identical with two other polyene macrolide antibiotics, candicidin (found by WAKSMAN et al. of Rutgers University in 1953 in *S. griseus*) and hamycin (found by THIRUMALACHAR et al. of Hindustan Antibiotics Research Institute in 1961 in *S. pimprina*). Its difference from them was shown by an HPLC comparison in 1980. Trichomycin shows activity against pathogenic *Candida, Trichomonas,* and *Trypanosoma* and has been used in vaginal applications to treat *Trichomonas vaginalis* infections.

223

Mithramycin [*18378-89-7*], (**223**), plicamycin, $C_{52}H_{76}O_{24}$, M_r 1085.17.

Mithramycin, recently renamed plicamycin, was found in the culture broth of *Streptomyces argillaceus* and *S. tanashiensis* by Abbott Laboratories in 1952 [358]. It is structurally related to chromomycin A_3. Mithramycin shows strong inhibitory activity against malignant cells of human origin. It acts by inhibition of the DNA-directed RNA synthesis through binding with DNA. Mithramycin is used intravenously to treat cancers of the embryonal cells, seminoma, choriocarcinoma, etc.

Lincomycin [*154-21-2*], (**224**), $C_{18}H_{34}N_2O_6S$, M_r 406.55.

224

Lincomycin was found in the culture broth of *Streptomyces lincolnensis* var. *lincolnensis* by the Upjohn Co. in 1962 [359]. It shows antibacterial activity similar to that of the macrolide antibiotics and also shows excellent activity against anaerobic bacteria. Lincomycin is used clinically in combination with other classes of antibiotics for postoperative, gynecological, urinary tract, ear and nose, and other infections.

Clindamycin [*18323-44-9*], (**225**), 7(*S*)-chloro7-deoxylincomycin, $C_{18}H_{33}ClN_2O_5S$, M_r 424.99.

225

Clindamycin was synthesized at the Upjohn Co. in 1966 by introducing a chlorine atom at the 7 position of lincomycin [360]. It is used as an orally active lincomycin-group antibiotic with the same range of activity as lincomycin. Clindamycin shows excellent activity against gram-positive bacteria and anaerobes, and it is used with other antibiotics for complicated infections.

Clindamycin palmitate hydrochloride [*25507-04-4*], (**226**), $C_{34}H_{63}ClN_2O_6S \cdot HCl$, M_r 699.87.

226

Clindamycin palmitate was synthesized by the Upjohn Co. in 1968 [361]. It has a much less bitter taste than clindamycin and is suitable for oral preparations for children. Clindamycin palmitate is very rapidly hydrolyzed into clindamycin after oral administration. Clindamycin phosphate [*24729-96-2*], $C_{18}H_{34}N_2O_8ClPS$, M_r 504.97, has been introduced clinically as an injectable clindamycin.

Flavophospholipol [*11015-37-5*], (**227**), moenomycin, bambermycin, $C_{69}H_{107}N_4O_{35}P$, M_r 1583.60.

Flavophospholipol, formerly called moenomycin, was found in the culture broth of *Streptomyces bambergiensis* by Hoechst in 1955 [362]. This drug is called bambermycin by INN and in the United States. It shows strong activity against gram-positive bacteria and weak activity against gram-negative bacteria. Flavophospholipol has been used as a feed additive for growth promotion in poultry.

Cycloserine [*68-41-7*], (**228**), $C_3H_6N_2O_2$, M_r 102.09.

228

Cycloserine was found in the culture broth of *Streptomyces orchidaceus* by Commercial Solvent Co. [363]. It was developed in collaboration with Eli Lilly & Co. in 1955 and is manufac-

Moenomycin A

227

tured synthetically. Cycloserine shows weak activity against gram-positive and gram-negative bacteria, including *Mycobacterium*. Its activity against clinically isolated tuberculotic bacteria, including streptomycin- and viomycin-resistant strains, is five to ten micrograms per millimeter. Cycloserine is used to treat tuberculosis caused by organisms resistant to other antituberculotic antibiotics.

Pecilocin [*19504-77-9*], (**229**), variotin, $C_{17}H_{25}NO_3$, M_r 291.39.

229

Pecilocin was discovered in the culture broth and mycelium of *Paecilomyces varioti* var. *antibioticus* by YONEHARA et al. of the University of Tokyo in 1959 [364]. It has an oily nature and shows activity against specific filamentous fungi. Pecilocin is used as an ointment or in ethanolic solution for the treatment of dermatomycoses caused by *Trichophyton, Microsporum,* and *Epidermophyton.*

Griseofulvin [*126-07-8*], (**230**), $C_{17}H_{17}ClO_6$, M_r 352.77.

230

Griseofulvin was discovered in the mycelium of *Penicillium griseofulvum* and other *Penicillium* species by OXFORD et al. in 1939 [210]. Its application in the treatment of fungal infections was initiated by ICI in 1946. Griseofulvin is used clinically by topical and oral administration for therapy of dermatomycoses caused by *Trichophyton* and *Microsporum* species.

Chloramphenicol [*56-75-7*], (**231**), $C_{11}H_{12}Cl_2N_2O_5$, M_r 323.13.

231

Chloramphenicol was found in the culture broth of *Streptomyces venezuelae* by EHRLICH et al. of Parke Davis & Co. in 1947 [212]. The effective industrial synthesis was developed in 1949, and the compound is manufactured synthetically. This was the third antibiotic to be introduced clinically and showed a wide range of activity against gram-positive and gram-negative bacteria, as well as *Treponema, Rickettsia,* and *Chlamydiae.* Chloramphenicol shows excellent activity in the treatment of dysentery and salmonellosis, and it is widely used against these diseases.

Chloramphenicol palmitate [*530-43-8*], (**232**), $C_{27}H_{42}Cl_2N_2O_6$, M_r 561.54.

232

Chloramphenicol palmitate was synthesized by Parke Davis Co. in 1952 [365]. It has a much less bitter taste than chloramphenicol and is suitable for oral administration, especially for children. The palmitate shows a higher serum level after oral administration than chloramphenicol does and acts the same as chloramphenicol in vivo.

Chloramphenicol sodium succinate [*982-57-0*], $C_{15}H_{15}N_2O_8Cl_2Na$, M_r 445.19, is highly soluble in H_2O and can be given by intravenous injection.

Mitomycin C [*50-07-7*], (**233**), $C_{15}H_{18}N_4O_5$, M_r 334.33.

233

Mitomycin C was found in the culture broth of *Streptomyces caespitosus* by WAKAKI in 1958 [216]. This followed the discovery of mitomycins A and B, derived from the same organism by HATA of the Kitasato Institute in 1956. Mitomycin C shows strong activity against a variety of tumors and bacteria. Because it decreases the concentration of leukocytes, its use had been limited, but after 1975 its low-dosage use in anticancer therapy in combination with other anticancer drugs increased.

Pyrrolnitrin [*1018-71-9*], (**234**), $C_{10}H_6Cl_2N_2O_2$, M_r 257.08.

234

Pyrrolnitrin was found in the cells of *Pseudomonas pyrrocinia* grown in a medium containing a high concentration of inorganic phosphate. It was discovered by ARIMA of the University of Tokyo in collaboration with Fujisawa Pharmaceutical Industries Co. in 1965 [366]. The same compound was found soon after that by Eli Lilly & Co. in the cells of *P. aureofaciens.* Pyrrolnitrin shows strong activity against a variety of fungi and weak activity against gram-positive bacteria. It is used topically to treat dermatomycoses caused by *Trichophyton, Epidermophyton,* and *Microsporum.* The antibiotic is unstable in sunlight and cannot be used to protect plants against phytopathogenic fungi.

Fosfomycin [*23155-02-4*], (**235**), $C_3H_7O_4P$, M_r 138.06.

235

Fosfomycin was found in the culture broth of *Streptomyces fradiae* by Compania Espanola de Penicilina y Antibióticos and Merck Sharp & Dohme in 1967 [219]. Its chemical structure is simple and unique among antibiotics in having a C–P bond. Fosfomycin shows antibacterial activity against gram-positive and gram-negative organisms, including *Pseudomonas aeruginosa* and *Serratia marcescens*, and β-lactam-resistant *Staphylococcus aureus.* Its mechanism of action is probably the inhibition of cell-wall synthesis. It shows no cross-resistance with other classes of antibiotics.

Fusidic acid [*6990-06-3*], (**236**), $C_{31}H_{48}O_6$, M_r 516.72.

236

Fusidic acid was found in the culture broth of a fungus imperfectus, *Fusidium coccineum,* by Leo in 1962 [220]. It has a steroid structure but shows no hormonal activity. Fusidic acid shows very strong activity against *Staphylococcus aureus* and weak activity against other gram-positive bacteria and gram-negative cocci and *Mycobacterium.* Its clinical use is restricted to staphylococcal infections resistant to other classes of antibiotics.

Bicozamycin [*38129-37-2*], (**237**), bicyclomycin, $C_{12}H_{18}N_2O_7$, M_r 302.29.

237

Bicozamycin, formerly called bicyclomycin, was found independently in 1972, in the culture broth of *Streptomyces sapporonensis* by Fujisawa Pharmaceuticals Industries and in that of *S. aizuensis* by MIYAMURA et al. of Niigata University [367]. It has a unique bicyclic structure and shows activity against *Klebsiella, Salmonella,* and *Shigella* but none against other gram-negative bacteria or gram-positive microorganisms. Bicozamycin is not absorbed

orally and shows very low toxicity; no mice died following its intravenous injection at a dose as high as two grams per kilogram. This drug is used orally to treat salmonellosis and dysentery.

Tiamulin [*55297-95-5*], (**238**), $C_{28}H_{47}NO_4S$, M_r 493.76.

238

Tiamulin was synthesized by Sandoz Co. in 1973, starting from pleuromutilin produced by *Pleurotus mutilus* [368]. It has been developed by that company in collaboration with E. R. Squibb & Sons for use against animal infections. Tiamulin is used against dysentery and *Mycoplasma* infections in sheep, swine, cattle, and chickens.

Siccanin [*22733-60-4*], (**239**), $C_{22}H_{30}O_3$, M_r 342.48.

239

Siccanin was found in the culture broth of *Helminthosporium siccans* by Sankyo Co. in 1962 [369]. It shows specific and strong activity against the dermatophytes *Trichophyton, Epidermophyton,* and *Microsporum,* but it has almost no activity against other fungi. Siccanin has been used as a topical ointment or solution to treat dermatomycoses.

5. Fermentation

Fermentation is considered here from the following points of view:

1) Biological development, which includes screening and selection, mutation, and maintenance of the strain.
2) Process development leading to large-scale manufacture.
3) Improvements in fermentation technology.

5.1. Screening

Technical developments in the production of penicillin have given the field new momentum and have stimulated the search, not only for more efficient strains, but also for microorganisms that produce completely different antibiotics. This process is called screening because valuable antibiotic producers are separated from the large number of organisms found in nature. The screening process and the expected results are influenced by several factors.

Source of Sample. Worldwide screening endeavors to isolate the individual microorganisms not only from soil samples from different sources, but also from other microbe-containing materials. Samples from unusual sources often show the occurrence of selection and adaptation. For example, thermophilic microorganisms are examined in samples taken from deep caves, the sea bottom, hot springs, or geysers.

Examination Technique. There are several factors that determine the conditions under which a certain microorganism not only lives and grows but also efficiently produces its antibiotic. These factors include the composition and pH of the culture medium, the additives, the air supply, and the temperature. These factors are also of prime importance for any later industrial fermentation. The isolation and testing of the new antibiotic, first in vitro and then in animal experiments, and the indisputable proof that the new compound is not identical to one of the numerous known antibiotics are part of the examination technique.

Purpose of the Examination. In the early days of antibiotic screening, any organism that showed antibiotic activity was screened, but later definite objectives were set and appropriate examination techniques were developed. The factors mentioned in the previous paragraph narrow

the choice to certain bacteria and fungi. Further restrictions are brought about by the selection of organisms used to test the efficacy of the antibiotic. Such specific screening methods are used to find, e.g., antifungal agents, antibiotics active against cancer or viruses, or antibiotics effective against bacteria resistant to other antibiotics.

A general overview of the successes and failures experienced during the search for antibiotics has been presented [370]. GOULDEN [371] reported that in the United States from 1955 to 1966, about 90000 synthetic compounds, 20000 plant extracts, and 120000 culture solutions of microorganisms were tested against different types of neoplasms. About 1600 substances showed sufficient activity to justify their purification; 31 fermentation products reached the first clinical test, but only five of them got as far as the second step. Of these only two products, mithramycin and streptonigrin, are clinically used today. It can be concluded that, starting with a limited number of samples, the probability of obtaining a therapeutic agent is extremely low. This also applies to other screening objectives, e.g., the search for antibiotics more effective against tuberculosis, resistant microbes, or fungi and yeasts. In order to realize a definite goal, new test methods had to be introduced. Asteromycin was discovered in the process of introducing new tests against mycoplasmas. A search for antibiotics active against bacteriophages led to the discovery of a strain producing dextrochrysin. Dienomycin was found when testing nucleotides with Wood's reagent. The leucopeptines, which are active against phytopathogenic microorganisms, gram-positive bacteria, and mycobacteria, were discovered as a result of their antiplasmin activity. Although all these antibiotics have not been approved for use, they show the importance of new screening methods.

5.2. Selection, Mutation, and Maintenance of Strains

The biological production of antibiotics is carried out predominantly by microorganisms. The discovery and isolation of the microorganism are the first steps of a long process leading to the production of the antibiotic. A yield-improvment program, a very time-consuming process, is needed to raise the yield of the strain to an economic level [372]. This is done primarily by developing optimal cultivation conditions, keeping in mind that the deep-tank and submerged methods are the only ones technically applicable. Even so, the concentration of antibiotic in the culture medium is generally not enough to start production.

For this reason *selection* is necessary. A large number of single individuals belonging to a strain are isolated. These are bred, and the antibiotic production in the cultures is quantitatively measured. New individuals with good, average, poor, or even no productivity usually develop. Hence, selection is carried out from generation to generation in an effort to develop a strain with as high an antibiotic productivity as possible, one that produces few interfering byproducts (dyes, toxins, other antibiotics, etc.), and one that remains stable over a long period of time, i.e., one whose antibiotic production does not decline.

Another technique used to obtain improved strains is *mutation.* Cultures are exposed systematically to mutagens, such as ultraviolet radiation or specific chemical compounds. The dosage is chosen so that of a very large number of treated individuals only a few survive, and these are genetically altered. The mutants obtained in this way are generally valueless. In a few cases, however, it is possible to separate a single organism that possesses properties, such as increased antibiotic production and strain stability, superior to those of the untreated strain.

Penicillin production has been perfected to such an extent that today's industrial strains produce at least 35000 U/mL of culture medium. On a smaller scale, still higher production rates have been obtained. The *maintenance* of the strain, i.e., the production, choice, testing, and storage of efficient antibiotic producers, plays a very important part in the manufacture of antibiotics. The yield of antibiotic tends to decrease through many successive rounds of selection. This tendency must be monitored using tests in culture plates, which include methods using the agar diffusion test, photocytometry, and tests in shaken erlenmeyer flasks or in small fermenters with volumes ranging from 10 to 3000 L.

5.3. Process Development Leading to Large-Scale Production

After an efficient microorganism has been found in the laboratory, the strain must be brought into large-scale production. This process, known as scaling up, is undertaken in steps and poses tremendous technical problems. Several factors are important in scaling up.

Transition to Larger Volumes. Microbial growth, begun in the laboratory on culture plates, transferred subsequently to shaking flasks having a maximum volume of one liter, and later to small industrial fermenters having a working volume of 3000 L, must ultimately be carried out in production fermenters having a total capacity of about 150 m^3 or more. The main problem involved in this process of scaling up is to modify the fermentation conditions in such a way that the same yields are obtained in the larger fermenters as in the smaller ones.

Changes in the Fermenter Geometry. The structure of the fermenter, its construction, and its dimensions, greatly affect the yield obtained. The height versus the diameter of the fermenter, the stirring and aeration systems, the cooling system (jacket, spiral, or inserted cooling), and the protection of the inlets and outlets of the fermenter against infection (pressure sealing) are all important factors in the fermentation process.

Experiments in large-scale fermenters are time consuming and expensive. Critical comparisons of similar experiments conducted by different institutes or companies must take into account the fact that the research laboratories have only a few types of fermenters at their disposal. In addition, almost every researcher handles similar fermentation problems using different strains of a microorganism. Hence, a real comparison cannot be made and only reserved conclusions can be drawn.

Variations in the Culture Medium or Nutrient Solution. The culture medium influences the growth of the microorganism and, independently of this, the amount of antibiotic it produces. The growth media or nutrient solutions required for the prefermentation treatment, which primarily must support the rapid multiplication of the microorganisms as a monoculture, have a different composition than the nutrient solution used during fermentation. For example, in fermentation the carbon source should not be too plentiful. As a result of rapid consumption, nutrients must be resupplied to prevent a nutrient shortage.

In the choice and supply of nutrients, factors other than the achievement of an optimal antibiotic production must be considered. A nutrient suitable for improving the yield of an antibiotic may simultaneously hinder its recovery. Only an accurate comparison of the yield with the effort required, from the prefermentation treatment to the final product, can decide whether an apparently good fermentation raw material is also suitable for production. The addition or removal of certain substances has a direct effect on the antibiotic production. In the manufacture of penicillin, the addition of building blocks or precursors to the fermentation broth causes, depending on the addition, a preferred production of benzylpenicillin (addition of phenylacetic acid) or of phenoxymethylpenicillin (addition of phenoxyacetic acid). On the other hand, if chloride ions are largely removed from the culture medium, e.g., by pretreatment with silver salts [373], [374], or by ion exchange [375], the production of chlortetracycline is suppressed in favor of tetracycline. Certain inhibitors, e.g., inorganic additives, such as bromides and thiocyanates [376], and a great number of organic compounds, also suppress the production of chlortetracycline.

Variation of Other Fermentation Conditions. Strict control must be maintained during fermentation. The temperature, the pH (including the effects of nutrients and additives on the pH), the stirrer speed, the air supply, and the duration of fermentation must be monitored constantly.

Control of Fermentation by Means of Additives. A resting surface culture or a simple shaken culture contains a definite nutrient medium, which is required to support the growth of the microorganism. The growing culture eventually slows down and ceases growth, usually because the medium is spent. A submerged fermenter allows the sterile addition of additives during the course of fermentation. In this way important changes can be made. A

sterile air supply and its generally continuous distribution are vital to all aerobic microorganisms. Any interruption of the air supply must be avoided and the air must be evenly distributed throughout the fermenter. This is achieved by a mixing and air-distributing system. The air supply is often limited in large fermenters as a result of high viscosity and foaming, which makes the addition of *antifoam substances* necessary (oils, silicones). Mechanical foam destroyers can also be used but they consume large amounts of energy and are not applicable in production plants. The addition of *nutrients*, in portions or continuously, permits the supply of nutrients to be adjusted at each stage in the fermentation process. The added nutrients may be organic (e.g., sugar as the carbon source) or inorganic (e.g., ammonia as the nitrogen source).

The pH can be adjusted during fermentation by the addition of *acid or base*. However, experience has shown that the addition of certain nutrients causes a simultaneous change in the pH. Slower adjustment is physiologically preferable in this case. The addition of sugar often causes a fall in pH because of carbon dioxide formation; peptides and amino acids cause an increase in pH (via the formation of ammonia or other nitrogen bases). The addition of *building blocks, precursors, and inhibitors* during the course of fermentation has proved useful, especially for the production of penicillins and tetracyclines. In such cases, a single addition at the beginning of the fermentation procedure leads to a concentration toxic to the fungus, but because of its rapid consumption, the precursor concentration should be maintained at a certain level.

Measurement and Control Techniques; Analytical Measurements during Fermentation. The process of fermentation is relatively long, and the antibiotic production is very sensitive to disturbances. Precise analytical measurements and rapid and accurate control mechanisms are therefore required.

The monitoring of conditions during the course of fermentation can be divided into direct measurements in or at the fermenter and indirect testing in the laboratory of samples withdrawn at regular intervals and under sterile conditions.

The direct measurements are immediate and can sometimes be automated. For example, an electrode could be installed to monitor the foam level and automatically release an antifoam additive as required. The formation of foam is influenced, within certain limits, by changes in the air supply. Equipment to monitor and control the temperature (by adjusting the amount of cooling water) and the pH of the medium is common. Some other direct measurements are the determination of the weight of the full fermenter, e.g., with the help of a pressure gage (especially at the start of fermentation and at harvesting), the measurement and control of the stirring speed and of the air supply, and the determination of the partial pressures of oxygen and carbon dioxide in the fermenter and their concentrations in the exhaust gas.

Computer monitoring is of great help in industrial production because of the large number and size of the fermenters. The results of measurements on indirect samples, which are available after hours or a few days, also are fed into the computer.

The tendency today is to analyze numerous fermentation samples, taken at as short intervals as possible, using automatic analyzing instruments for sugar, nitrogen, phosphates, biomass, product, etc. Methods that permit the fully automatic withdrawal of samples during fermentation and the automatic transfer of the samples to different analyzers have been perfected.

Scale Down. When a fermentation procedure is carried out for the first time on an industrial scale, scale-up problems occur. After their start-up problems have been overcome, large fermenters often produce disproportionately larger amounts than the previously used smaller fermenters. It is difficult to explain this phenomenon when the same strain and approximately the same fermentation conditions are used. This leads to the scale-down problem, i.e., the problem of increasing the yield obtained from the smaller fermenter to that of the larger.

Solution of the scale-down problem is very important for the further development of a strain. A new, promising mutant or variant developed during a large-scale fermentation must first be evaluated in a small fermenter. The yield thus obtained must be comparable to the yield obtained using the original production strain, also in a small fermenter.

Continuous Fermentation. Continuous fermentation has proved to be feasible in breeding yeast, in the activated-sludge purification of waste water, and in the brewing of beer [377], [381]. Continuous industrial production of antibiotics suffers from several difficulties, and it has made little progress in displacing batch methods.

1) It is very difficult to keep the yield constant. The highly efficient strains used today tend to degenerate; i.e., the antibiotic production declines. This process makes the maintenance of the strain very important.
2) Maintaining the sterility of the fermentation environment and the additives is much more difficult than in a batch process.
3) A purely technical problem is the continuous accumulation of culture solutions; this generally necessitates continuous further processing. It therefore becomes necessary to convert a factory normally working only days into one working round-the-clock shifts.
4) The main saving in introducing a continuous process lies in the reduction of the volume of the equipment. However, the extent of space saving is directly proportional to the rate of the reaction. When the time required for fermentation is two weeks or less, then the volume of equipment required for a continuous process is scarcely less than that needed for a batch process. In addition, the construction of the equipment required for a continuous process is more complicated and more expensive.

Even in the case of antibiotics produced by fast-growing bacteria, e.g., tyrothricin [382] and gramicidin S [383], reasons 1, 2, and 3, along with higher equipment and factory costs, speak against continuous production.

5.4. Fermentation Technology

The essential prerequisites for the production of antibiotics using either submerged fermentation or other fermentation methods are the same.

1) A strain of microorganism should produce the desired antibiotic in satisfactory amounts and, as far as possible, without unwanted byproducts that are difficult to remove. It strain should be as stable as possible; i.e., the production of antibiotic should not decrease with time. The strain should also be resistant to other microorganisms, phages, etc.
2) Complete industrial facilities, which include laboratories for the preparation of inoculum and for the maintenance of the strain and vessels for the prefermentation treatment and for fermentation, must be available. The vessels must be equipped with devices such as temperature regulators, automatic foam destroyers, and appliances for the addition of nutrients and for the supply of sterile air. In addition, a sufficiently large recovery plant and enough storage space for raw materials, fermentation aids, intermediates, and finished products must be available.
3) The fermentation process and its optimal operation, the properties of the antibiotic formed, its isolation, and its efficient purification must be known in detail.
4) Analytical equipment and methods to monitor the operation of the fermentation and recovery processes and to control the raw materials, intermediates, and end products must be available.

Figure 1 shows a schematic outline of the large-scale production of penicillin, an example of a fermentation process.

5.4.1. Maintenance of the Strain and Production of Inoculum

The strain of microorganism is maintained as a pure culture in a microbiological laboratory. The underlying principle is preservation; i.e., a form of the microorganism that is as stable as possible must always be available. The microorganism is stored in a large number of small, separate ampules or vials that are used successively. Cultures of good colonies are constantly restarted so that the strain is never depleted.

If the microorganism forms spores, its storage is relatively easy. The spores, a resting form, are dried, usually mixed with sterile soil, and stored in ampules. Spores can be stored for months or years.

The application of frozen inoculum, stored in the vegetative state, has advantages. This form

Figure 1. Schematic outline of the manufacture of penicillin
a) Antifoam substance; b) Steam; c) Precursors for penicillin formation; d) Condensate; e) Air; f) Air filter; g) Air-flow recorder; h) Cooling brine; i) Cooling water; k) Spore culture (filled into l); l) Fungal culture with spores; m) Spore suspension; n) Prefermenter (inoculation culture for o); o) Intermediate fermenter (inoculation culture for p); p) Production fermenter; q) Cooling tank; r) Filtration unit; s) Filtrate container; t) Starting vessel for nutrient solution; u) Pump.

is easy to prepare in large amounts and germination is no longer necessary. However, the storage times are limited.

The inoculum for penicillin fermentation is produced by placing the spore-containing soil in a sterile agar nutrient medium in Roux bottles and incubating at 24 °C. The spores germinate in one or two days (vegetative form). A rich mycelium network is formed, from which new spores develop in a few days. These young, freshly formed spores are removed from the fungal network under sterile conditions and with water or normal saline. They are then transferred to erlenmeyer flasks containing a suitable sterile nutrient solution. The suspension of spores is shaken at 24 °C, enabling them to undergo multiplication.

The inoculum is transferred to another shaken flask and is allowed to grow in nutrient solution until a submerged culture can be started. The next steps (Fig. 1) lead to rapid growth and an increase in volume until finally enough mass of mycelium is obtained to inoculate the production fermenter.

Besides breeding the inoculation material, the microbiology laboratory has the equally important task of guaranteeing the maintenance and care of the strain, which insures a steady supply of a microorganism with a constant efficiency. If the laboratory limited itself to breeding, storage, and regular reinoculation, the antibiotic activity of the fermentation cultures would very soon decrease because these highly productive strains tend to mutate and degenerate. To avoid a decrease in the antibiotic production in industrial fermentation, efficient strains must be subjected annually to several thousand single selections, and the resultant colonies must be tested. The single strains thereby isolated show considerable differences in their stability, i.e., in

their tendency to develop into good or bad producers or even into nonproducers. Only after the minimum number of selections necessary for the maintenance of a strain has been exceeded, do the chances of surpassing the efficiency of the original strain increase. Then an improvement in the factory productivity becomes possible.

5.4.2. Treatment Before and During Fermentation

The manufacture of antibiotics by means of fermentation is always carried out in closed, sterile vessels constructed of stainless steel or of steel lined with stainless steel. Figure 2 shows a typical construction.

Figure 2. Schematic outline of a fermenter

The supply of sterile air for fermentation is very important. Foreign organisms are filtered from the air by means of glass wool, a filtering candle, or other methods.

The composition of the nutrient solutions must meet the nutritional needs of the microorganism; these needs vary depending on the stage of fermentation. The solutions are produced in separate vessels and are sterilized therein, in the fermenter itself, or in a continuous-flow heat exchanger. This heater is also used to sterilize the additives [380].

The amounts of raw material required may only be transported and stored in silos. Hydraulic transport and weighing with a pressure gage have replaced conventional methods, and only minor additives, e.g., trace element salts, are weighed in the normal way.

Balance Studies. The balance of energy and materials in the particular case of benzylpenicillin has been described [384] The manufacture of 100 kg of the sodium salt of penicillin requires 1.2 t carbohydrates, 60 kg animal and vegetable fats, 770 kg cornsteep liquor, 220 kg inorganic compounds (buffer, sources of sulfur and phosphorus), and 100 kg phenylacetic acid as precursors. The amount of product and the distribution of energy are shown in Table 1.

Table 1. Balance of energy and materials

	Mass, kg	Mass fraction, %	Energy distribution ∗, MJ
Raw materials	2350	–	–
Products			
benzylpenicillin sodium	100	4	2453
Fungal mycelium	825	35	11744
Remaining substance in culture medium	660	28	8051
Carbon dioxide ∗∗	765	33	13176
Total			35424

∗ as heat of formation or combustion.
∗∗ Heat of combustion released during transition to carbon dioxide (carried off with the spent air or cooling water).

The energy requirements for the production of 100 kg of benzylpenicillin sodium are:

Electrical energy:	10.8 GJ (mainly for stirring)
Steam:	4 t (sterilization, sealing)
Fermentation air:	50000 m^3 (at STP)
Cooling water:	900 m^3

Waste Materials. The accumulation of substantial amounts of fermentation waste materials, such as the fungal mycelium and the culture solution freed of antibiotic, is a real problem. After the removal of organic solutions, e.g., by distillation (stripping), the spent medium must be fed into a biological water treatment plant. Seepage is no longer allowed.

The fungal mycelium can be processed or disposed of in several ways.

1) It can be fed to animals, directly or after drying. The proceeds cover only a part of the costs, especially if the mycelium has been dried. Also, the presence of antibiotics in the

filter cake must be avoided, and filtering aids, e.g., kieselguhr or activated charcoal, may not be used.
2) It can be incinerated after the addition of liquid fuel; this is a clean but very expensive procedure.
3) It can be disposed of by dumping and humus production along with sludge depositing. This alternative often must be considered, although it entails high transportation costs.
4) It can be recycled. The mycelium can be used, directly or after intermediate processing, as a raw material for further fermentation. Mycelium is usually used as a nutrient for another microorganism. This approach is economically attractive (see Table 2 [385–392]).

Control of the Fermentation Process. At regular intervals of several hours, samples of the culture solution are withdrawn through the sample port for analysis. Important data are obtained by means of chemical, physical, and biological tests. The values are plotted and curves that present a good picture of the fermentation process are obtained.

The most important analyses are:

1) Determination of the amount of antibiotic. (Biological assay is described on 7.)
2) Determination of the weight of the mycelium as an indication of the growth of the microorganism. After inoculation of the fermenter and an initial slow phase, rapid multiplication occurs. This slows down later and finally almost comes to a standstill. The point in time at which the antibiotic production decreases and falls short of economic viability can be empirically determined. At about this point the fermentation is interrupted and the culture harvested.
3) Microscopic control of the growth of the microorganism.
4) Sterility tests, i.e., tests for the absence of foreign microorganisms.
5) Measurement and correction of the pH of the culture.
6) Determination of sugar. Figures 3 A and 3 B graphically show two possibilities. Figure 3 A shows the sugar consumption. The amount of sugar consumed, plotted against time, is the difference between the total amount of sugar added and the analytically determined sugar concentration at that particular time. Figure 3 B shows the sugar content of the nutrient solution. Here, the shape of the curve is a measure of the sugar consumption (provided no more sugar is added).
7) Determination of nitrogen in the mycelium and in the culture solution, possibly combined with the addition of a nitrogen-containing nutrient solution.

6. Isolation and Purification of Antibiotics; Quality Specifications

6.1. Isolation

When fermentation is completed, i.e., when a sufficiently high amount of antibiotic has accumulated in the culture solution, the antibiotic must be separated from the spent medium. The contents of the fermenter are transferred to a harvesting tank so that the fermenter can be turned immediately to the production of the next batch. The aeration is stopped, the solution cooled if necessary, and recovery of the product is begun as soon as possible. If permitted, a disinfectant, e.g., formaldehyde, is added or heat is applied to prevent further proliferation of the microorganism.

The recovery of the antibiotic can be carried out in several different ways, depending not only on its properties, but also on its subsequent processing.

Drying Process. Technically speaking, the easiest and cheapest process is to dry the entire culture, the culture filtrate, or the filter cake. Drying is employed on a large scale only in the manufacture of antibiotics used to supplement animal feed, e.g., tetracyclines and moenomycin (flavophospholipol, flavomycin) or salinomycin. Spray drying is the method most often used. Other methods, such as roller drying (possibly under vacuum) are also used. It is advisable to concentrate the solution, e.g., using a downdraft evaporator, before it is actually dried. In any case, the antibiotic must be resistant to higher temperatures. Because of its very short heating time, the spray-drying method is one of the most gentle procedures.

Table 2. Fermentation residues used as raw material for further fermentation

Fermentation residue	Condition	Raw material for subsequent fermentation	Reference
Penicillium (from benzylpenicillin)	moist mycelium	oxytetracycline	[385]
	moist mycelium	chlortetracycline	[386]
	moist mycelium	streptomycin, vitamin B_{12},	[387]
		or riboflavin	
	mycelium hydrolyzate	phenoxymethylpenicillin	
Penicillium or other mold mycelia	mycelium hydrolyzate	nutrient medium (e.g., for	[388]
from fermentation		*Lactobacillus bifidus*)	
Penicillium (from benzylpenicillin)	moist mycelium	calcium gluconate	[389]
Streptomyces (from tetracyclines)	moist mycelium	tetracyclines, etc.	[390]
Penicillium, *Aspergillus*, *Rhizopus*,	moist mycelium	nisin, in connection with lactic	[391]
or yeast		acid fermentation (silage)	
Penicillium, *Aspergillus*, *Actinomyces*, *Rhizopus*, yeasts, and activated sludge (from water treatment plants)	moist or dry mycelium	moenomycin (flavophospholipol)	[392]

Figure 3. A. Penicillin formation with continuous glucose addition after development of the mycelium [393]
B. Streptomycin formation by *Streptomyces griseus* [394]

Filtration Followed by Extraction and Precipitation. The mycelium is separated from the liquid medium by passing the entire culture solution through a filter press, using filtering aids if necessary. A rotating filter can also be used e.g., an Oliver filter, which has three zones, intended for suction, washing, and peeling. If the culture solutions contain small amounts of mycelium, separation can also be carried out in a centrifuge.

Extraction is the method used to separate most antibiotics contained in the filtrate. A classic example is the extraction of benzylpenicillin (and phenoxymethylpenicillin) with butyl acetate (Fig. 4). It leads to a 120- to 150-fold enrichment. The penicillins are then precipitated from the extract as salts. Only those organic bases that preferentially form sparingly soluble salts with penicillin G or V but highly soluble salts with other penicillins can be used for precipitation from either water or organic solvents.

Tertiary morpholines, *N*-ethylhexahydropicoline and *N*-ethylpyrrolidine, besides *N*-ethylpiperidine, can be used for precipitation from butyl acetate, amyl acetate, and similar esters. *N*-Ethylhexamethyleneimine is used for precipitation from chloroform.

The salts thus obtained generally are easily crystallized easily and are quite stable in the dry state. They can be stored until further production steps are carried out to give the product that is used in clinical practice.

Filtration and Direct Precipitation. After filtration the aqueous culture filtrate can be subjected to direct precipitation. This method was once important in the isolation of streptomycin as a highly insoluble, colored salt, but this use has long been abandoned. Direct precipitation from the culture filtrate is of interest now because the amount of antibiotic produced by today's highly developed, efficient strains is so large that the traces of antibiotic remaining in the aqueous solution after precipitation are negligible. This method has acquired importance in the isolation of, e.g., tetracycline, which can be precipitated at its isoelectric point (pH 4.8) [395]. Another example is the direct precipitation of 5-hydroxytetracycline using a long-chain quaternary ammonium salt [396].

Filtration Followed by Extraction from the Filter Cake. If the antibiotic is present entirely or almost entirely in the mycelium, its isolation is greatly facilitated by filtration, which causes a considerable decrease in the volume of material. The moist or dry filter cake bearing the product is extracted with a solvent. The resulting solution is filtered again and processed further [397]. Examples are griseofulvin and moenomycin (flavophospholipol, flavomycin).

Adsorption Methods. Adsorption on activated charcoal following filtration is no longer used industrially. However, this method is used with some success in the developmental stages of new antibiotics.

Direct adsorption, e.g., on resins, without prior filtration, is still industrially important for the separation of such basic antibiotics as streptomycin, kanamycin, neomycin, and paromomycin. Filtration of the culture solution, especially because of the slimy substances produced by actinomycetes, is laborious and requireds large amounts of filtering aids. The real breakthrough came when the adsorption material (cation exchanger) was brought into contact with an ascending stream of the culture solution, without prior filtration. In this case the antibiotic molecules leave the solution and attach themselves to the surface of the adsorption material.

6.2. Purification Techniques, Sterile End Products, Official Regulations

Antibiotics are fermentation products and are isolated either as unfinished products or as intermediates, generally solid substances of limited stability. They are purified by methods normally employed in organic chemistry, which include chromatography, crystallization, and precipitation.

A major requirement is that the antibiotics intended for parenteral administration be free of pyrogens (fever-producing substances) and histamine-like compounds. These unwanted substances can be carried over from the fermentation, but such impurities must not appear in the final product. Special purification steps, e.g., treatment with elemental chlorine (destruction of pyrogens associated with streptomycin), filtration through activated charcoal, or deep-bed adsorption filtration, must be carried out. Precise

Figure 4. Penicillin extraction and the sterile final stage
a) Rotameter; b) Mixer

tests must confirm the absence of all unwanted substances.

In the manufacture, purification, and preparation of antibiotics, special measures also must be taken to prevent penicillin contamination. In the processing of active substances to give pharmaceuticals, a strict spatial separation is necessary to avoid mutual contamination through the air.

Even minute amounts of antibiotics, especially penicillin, can lead to sensitization in humans and to the formation of resistant microorganisms. These antibiotics are then ineffective in the treatment of diseases because either the patient is allergic or the pathogens have become resistant. Therefore, during the processing and filtering operations the air supply must be monitored very carefully to insure the protection of the operating personnel and to guarantee that no patient unintentionally receives even traces of penicillin with another drug.

Production of Sterile Bulk Drug Substances. If sterile bulk drug substances are required, then aseptic conditions must be maintained from the start of the process. Many antibiotics are chemically unstable and cannot tolerate sterilization by heat or other agents. Generally, the solution is sterilized before the final crystallization, precipitation, spray drying, or freeze drying. This is done by filtering through porcelain filters, sintered metal filters, layers of filter paper, or graded-porosity films.

Work is carried out in specially equipped sterile rooms, which are fully air conditioned with practically germ-free air. Air-filtering devices similar to those used for the production of fermentation air are used. The rooms are disinfected using, e.g., gaseous formaldehyde, before work is commenced. The floor is kept damp with a solution of a disinfectant (phenol, quaternary ammonium bases) mixed with glycerol, to control dust. The air pressure in these sterile rooms is higher than atmospheric pressure. This prevents the entrance of unclean air. One enters the sterile rooms only after carefully washing and donning sterile clothes and through an airlock equipped with UV lamps and foot mats soaked in disinfectant. Small objects (tools, etc.) are brought into the sterile room through smaller air locks, in which they are disinfected using intense UV radiation. Containers, e.g., stainless steel cans, are first washed thoroughly and then sterilized

in an autoclave. The autoclave is provided with one door that leads to the unsterile washing room and a second door leading to the sterile room.

The different steps in the course of further processing the antibiotics, such as centrifugation, drying, pulverization, sieving, and packaging, are performed in sterile glove boxes, which are provided with sterile air at a slightly elevated pressure and are equipped with UV irradiators.

Laminar-Flow Technique. In this technique, only one part of a clean or sterile room is maintained as a clean bench. This area is surrounded by a sterile box provided with a working access. To avoid the penetration of unclean air into this confined clean space, a displacing, turbulence-free air stream is created in the box. A continuous stream of sterile, filtered air enters the box from the top or from one side at a fixed speed. This air is distributed uniformly and is then sucked out the opposite side at the same speed. Special devices insure that there is minimum turbulence in the area of contact between the flowing, sterile air and the stationary, unclean air. Laminar-flow (LF) units can also be used for work with substances that should not escape to the outside world. In this case the air is recirculated through a filter.

Clean Packing. Antibiotics packed in bulk, in large containers, and intended for therapeutic use, usually are present in a sterile, highly pure state. Products such as tetracycline hydrochloride, intended for oral administration, must be very pure but not necessarily sterile.

Official Quality Requirements, Pharmacopoeias. The production process and the quality of the end product are subjected to rigorous official controls. The requirements have long been stipulated in the pharmacopoeia of each country and generally possess legal authority. The pharmacopoeias *European Pharmacopoeia, International Pharmacopoeia,* and *Compendium Medicamentorum* (standard pharmacopoeia for all Comecon states) are each valid in several countries.

In the United States, the influence exerted by the federal government goes beyond the determination of minimum quality standards for drugs. The Food and Drug Administration (FDA), attached to the U.S. Department of Health and Human Services, has published a Code of Federal Regulations (CFR) that is continuously supplemented with new regulations and reissued annually. The demands on the quality of a drug are substantially stricter and more comprehensive than those stipulated in the *U.S. Pharmacopeia.* In addition, detailed requirements have been established for the production and encapsulation techniques and rooms, the documentation, and the storage of raw materials, additives, intermediates, and end products. A detailed analysis of the starting materials, process controls, and tests of the end products and preparations must also be carried out. When a product not yet approved by the FDA is to be registered, preliminary tests must be conducted as well.

Food and Drug Administration officials have the right to inspect production plants regularly. Complaints can lead to the temporary closing of the plant and to the recall of certain preparations or particular batches of a preparation. In order to achieve a uniform standard in the production of drugs, the FDA [398] and the WHO [399–402] have elaborated and published fundamental rules that are now internationally called Regulations for Good Manufacturing Practices (GMPs). Drugs manufactured in countries outside the United States but imported into the United States are also subject to FDA regulations, including the GMPs, and FDA inspections. The FDA has published detailed rules in the *Federal Regulations* [403], especially for the registration of imported products.

Officials in other countries also demand a detailed description of the manufacture, quality, and safety of any drug they import. In many cases, sales depend on a prerequisite inspection of the factory, similar to the one conducted by the FDA. Canadian officials, American military forces purchasers, and the British Department of Health and Social Security all have this requirement.

7. Analytical Measurements and Quality Control

The analyses of antibiotics can be divided into two basic groups:

1) Tests during production, usually process surveillance and control.

2) Quality control, practiced as required by the WHO and the FDA. These tests have been routinely conducted by independent laboratories for a long time.

The end product, raw materials, and intermediates all are tested. The analytical measurements can be divided into chemical and physical tests, on the one hand, and biological tests, on the other. For the former, general methods used in synthetic organic chemistry are applied, along with some special methods that have been worked out for antibiotics. Fully or partially automatic techniques have been introduced to handle the large number of samples.

7.1. Microbiological Analysis

Biological Assay. Numerous microbiological methods are available to determine the amount of antibiotic present in a sample.

Agar Diffusion Test (Cylinder-Plate Method). See [404] for the original method; improvements are described in [405], [406].

A standard method has been published by the FDA [407]. For supplements, see [408] and [409].

Twenty milliliters of nutrient agar is placed in a flat-bottomed petri dish. After this solidifies, four milliliters of a second nutrient solution, seeded with the test bacteria, is poured evenly onto the first layer (at 48 °C). As soon as the second layer has solidified, six sterile stainless steel cylinders are placed on the agar, preferably using a cylinder-placing machine. To the open cylinders are added equal amounts of a standard penicillin solution containing 2.0, 1.5, 1.0, 0.5, and 0.25 U/mL. Samples of the test antibiotic solution are deposited analogously on other petri dishes.

The dishes are incubated at 37 °C for 16 – 18 h. During this time the penicillin diffuses out of the cylinders into the surrounding agar and suppresses the growth of the test organism. Thus, the cylinders are surrounded by clear zones, free of bacteria. The diameter of each zone provides an index of the activity of the penicillin preparation. The mean values obtained from 10 – 20 standard plates are used to draw a calibration curve, and the biological activity of the test solution in international units is determined using conversion tables.

Antibiotic Disk Method. This is a modification of the diffusion test. The method is widely used to determine whether a definite strain or a mixture of different microorganisms is sensitive or resistant to a given antibiotic [410–415].

The pathogen is freshly isolated from patients and used to inoculate a suitable nutrient agar plate. Filter paper disks 6 or 9 mm in diameter are placed on the petri dish before incubation. These disks are impregnated with a solution of the antibiotic. The amount is chosen so that the concentration of active substance present after diffusion into the agar medium corresponds to the level attainable in the patient (blood or tissue level). Test doses of 0.5 to 20 U are normal for a disk test of penicillins G or V.

In order to maintain a certain uniformity in the production of the nutrient medium for the disk method, the following directions for the preparation of peptone – casein agar have proved useful:

Peptone	6.0 g
Pancreatic – digested casein	4.0 g
Yeast extract	3.0 g
Meat extract	1.5 g
Dextrose	1.0 g
Agar	15.0 g

Table 3. Diameter of zones of inhibition for *Staphylococcus aureus* ATTC 6538 P

Antibiotic	Concentration per disk	Inhibition zone
Ampicillin	5 µg	26
Chloramphenicol	10 µg	20
Lincomycin	2 µg	19
Methicillin	10 µg	26
Novobiocin	10 µg	26
Oxacillin	10 µg	30
Penicillin (P)	0.5 I.U.	26
Penicillin (∗ P) [a]	20 I.U.	>40
Streptomycin [b]	10 µg	16
Tetracycline	10 µg	27

[a] Massive dose of penicillin (see Fig. 5);
[b] A pH of 8.0 is required for the optimal evaluation of the substance. Under these conditions the diameter of this zone is also 26 mm.

The components are dissolved in 1000 mL of distilled water and the pH of the liquid agar is adjusted to 6.55 after sterilization. If an agar plate thus prepared is incubated, the growth of

the microorganisms seeded on the plate can be observed from the turbidity of the agar surface. If the antibiotic on the disk is effective, a clear zone of inhibition forms surrounding the disk (Fig. 5). Table 3 shows the experimental values for the diameters of the zones of inhibition for *Staphylococcus aureus* ATTC 6538P, using the pH 6.55 nutrient medium described above.

Figure 5. Antibiotic disk test
The diameter of the clear zone depends on the test dose of antibiotic: disk P (left) contained 0.5 U, disk ∗P (right) 20 U benzylpenicillin sodium.

Tube Dilution Method. Three milliliters of a nutrient solution is put into each of a row of tubes. Three milliliters of a penicillin solution with a dilution of 1 : 100 is pipetted into the first tube. After thorough mixing, three millimeters is removed and added to the next tube. After mixing, three millimeters is removed and added to the third tube, and so on. The tubes contain successively lower concentrations of the drug. If the initial penicillin solution had a 1 : 100 dilution, the first tube now contains a 1 : 200 dilution, the second a 1 : 400, and so on.

Each tube is inoculated with one drop of a day-old *staphylococcus* culture (test bacteria). After incubation for one day at 37 °C, the end point is determined, i.e., the lowest concentration of penicillin that prevents the development of turbidity. If tube 3, for example, is clear but tube 4 is turbid, the end point is calculated by multiplying the starting dilution of 1 : 100 by 2^3. Thus the bacteriostatic units are obtained, here 800 Bact. U. These can be converted into international units with the help of the penicillin sensitivity factor. For instance, if this factor is 0.04, then 25 Bact. U = 1 I. U. and the solution contains 800/25 = 32 I. U. [416–419].

Slight turbidity also can be caused by protein precipitation resulting from a change in pH. For this reason, it is advisable to add a pH indicator to the nutrient broth. Changes in the pH are then clearly visible. Phenol red and bromothymol blue generally are used. A critical assessment of the test is given in [408].

The tube dilution method is also used to determine the sensitivity of freshly isolated single strains or mixtures of pathogens to antibiotics. A comparison of the lowest inhibitory concentration of an antibiotic with the serum levels attainable in vivo indicates which antibiotic is most suitable for clinical administration.

Automatic Analyses. Automatic sample removal and preparation have speeded up analyses. However, in cases that involve special preparatory steps, such as dissolution, filtration, or extraction, full automation is not yet possible. Many references discussing automatic biotesting, are available [408], [409], [420–425].

The measurement of the clear zones in the agar diffusion test, which formerly was conducted visually, can now be performed objectively and automatically using commercially available instruments (scanning analysis systems). By connecting a laboratory calculator (e.g., HP 85) to such an instrument, the amount of antibiotic in a test solution can be calculated using reference standards and printed out directly.

7.2. Isotopically Labeled Antibiotics

Antibiotics containing a radioisotope at a definite position in the molecule are very important for scientific studies. Labeled substances can be used to trace:

1) Accumulation in specific tissues, e.g., tumors, for diagnostic purposes.
2) Metabolism of an antibiotic, i.e., tracing the metabolites and cleavage products in animal and human organs or excretions.
3) Determining the location and partial degradation of the antibiotic during further fermentation, processing, and purification steps.

Isotopically labeled antibiotics can be manufactured in two ways.

Fermentation Production. If appropriate isotopically labeled compounds are added to the culture solution during fermentation, a corresponding amount of labeled antibiotic is produced and can be isolated with the unlabeled antibiotic. This technique also is suitable for following labeled precursors, nutrients, salts, etc., during the fermentation procedure. In this way, insights into the mechanism of formation of the antibiotic in a microorganism or the mechanism of formation in the presence of an isolated enzyme system can be obtained. Benzylpenicillin, phenoxymethylpenicillin, and 6-aminopenicillanic acid have been labeled with ^{14}C and ^{35}S in this way [395, vol. 4, pp. 266, 296], [426]. Streptomycin has been labeled with ^{14}C and ^{3}H [395, vol. 4, p. 349].

Labeling. Acylation of 6-aminopenicillanic acid with a ^{14}C-labeled acid yields a product labeled in the side chain [427]. A subsequent isotopic exchange within the antibiotic molecule is also possible. However, only the easily removed ^{1}H atoms can be replaced by ^{2}H or ^{3}H.

8. Economic Aspects

Antibiotics find widespread use in human and veterinary medicine. As yet, agricultural usage is low and generally confined to Asia where they are used for antifungal treatment of rice plants, etc. Over 30 kt/a of antibiotics was produced worldwide in 1984. There are six main categories of antibiotics:

1) β-Lactam
2) Tetracycline
3) Macrolide
4) Peptide and glycopeptide
5) Aminoglycoside
6) Polyether

At least twenty other commercial antibiotics are not included within these six categories. They belong to a variety of chemical types, i.e., polyene, ansamycin, anthracycline, nucleoside, etc.

Over the past ten years, output has grown by approximately 4 % per year, with the most rapid growth in the β-lactams, macrolides, and polyethers. On the other hand, tetracyclines have presented a static or declining market, particularly for human therapy. Dollar volume sales have grown correspondingly, with a successful new human antibiotic product being defined as one commanding minimal sales of \$ 100 000 000 worldwide. β-Lactam sales account for at least half of the total human antibiotic market, which exceeds \$ 5 000 000 000.

All the categories except the polyethers find use in human medicine. The most important veterinary antibiotics belong to the tetracycline, macrolide, peptide, and polyether families although some β-lactams, aminoglycosides, and other antibiotics also have veterinary markets.

Worldwide, there are over seventy primary producers of antibiotics by fermentation. If companies involved in producing semisynthetic penicillins and cephalosporins from purchased parent antibiotics are included, the number is well over one hundred. Some companies specialize in the production of a single antibiotic, but more generally a number of different antibiotics are produced, e.g., benzylpenicillin, phenoxymethylpenicillin, cephalosporin C, oxytetracycline, and streptomycin. Large multinational pharmaceutical companies frequently operate a number of separate antibiotic fermentation plants in one or more countries. For technical reasons, it may not be possible to produce two different antibiotics in the same plant.

United States and European companies are active in all categories of antibiotics; Japanese, Chinese, and Korean producers have tended to specialize in the aminoglycosides, macrolides, anticancer drugs, semisynthetic second- and third-generation β-lactams, and agricultural antibiotics.

Some old antibiotics, which are no longer protected by patents, are traded in bulk at the prices quoted in the following paragraphs. The bulk products are purchased for use in specialities or conversion into semisynthetic drugs by companies that do not have their own fermentation facilities or whose fermentation capacities are not adequate to supply their growing needs. Bulk antibiotics are also purchased on tender by government agencies, charities, etc., for use in developing countries. There is usually a significant difference between a bulk price and that of a finished (branded or generic) speciality.

In the following paragraphs the estimated worldwide antibiotic output for the year 1985

is listed. The antibiotics are grouped into the six main categories plus "other antibiotics." The production figures include antibiotics for human and veterinary applications. The specific compounds are arranged alphabetically, not according to their commercial importance. The bulk prices are quoted only for the antibiotics that are traded; this price is much lower than the price of the finished specialty product.

β-Lactams. Total output is 10 – 20 kt/a. There are over 50 producers. The bulk price for benzylpenicillin is 25 – 30 $/kg. The following compounds are included: ampicillin, amoxycillin, carbenicillin, cefaclor, cefamandole, cefazolin, cefoperazone, cefotaxime, cefoxitin, ceftazidime, cefuroxime, cephadroxil, cephalexin, cephalosporin C, cephalothin, cephamycin C, cephradine, clavulanic acid, cloxacillin, dicloxacillin, flucloxacillin, oxacillin, benzylpenicillin, phenoxymethylpenicillin, piperacillin, and ticarcillin.

Tetracyclines. Total output is 5 – 10 kt/a. There are 30 – 40 producers. The bulk price for oxytetracycline is 25 – 30 $/kg. The following compounds are included: chlortetracycline, democlocycline, doxycycline, methacycline, minocycline, oxytetracycline, and tetracycline.

Macrolides. Total output is 3 – 5 kt/a. There are 20 – 30 producers. The bulk price for erythromycin base is 100 – 120 $/kg. The following compounds are included: erythromycin, ivermectin, josamycin, kitasamycin, midecamycin, milbemycin, miocamycin, oleandomycin, spiramycin, and tylosin.

Peptides and Glycopeptides. Total output is 2 – 3 kt/a. There are 10 – 20 producers. The bulk price for bacitracin is 15 $/kg. The following compounds are included: avoparcin, bacitracin, colistin, enramycin, gramicidin, nisin, polymixin, and thiopeptin.

Aminoglycosides. Total output was 1 – 2 kt/a. There are 20 – 30 producers. The bulk price for streptomycin is 30 $/kg. The following compounds are included: amikacin, apramycin, dibekacin, dihydrostreptomycin, gentamicin, hygromycin, kanamycin, lincomycin, neomycin, netilmicin, paromomycin, ribostamycin, sagamicin, sisomicin, streptomycin, and tobramycin.

Polyethers. Total output is 3 – 5 kt/a. There are 5 – 10 producers. The following compounds are included: laidlomycin, lasalocid, maduromycin, moenomycin, monensin, narasin, and salinomycin.

Other Antibiotics. Total output was 1 – 2 kt/a. There are 30 – 40 producers. The following compounds are included: amphotericin, anticancer (including bleomycin, daunorubicin, doxorubicin, epirubicin, and mitomycin), blasticidin, clindamycin, cycloserine, flavomycin, fusidic acid, griseofulvin, novobiocin, nystatin, pimaricin, pleuromutilin, pyrrolnitrin, rifampicin, spectinomycin, vancomycin, viomycin and virginiamycin.

Abstract

The article contains sections titled:

1. Introduction
2. Stimulators of Insulin Secretion
2.1. Sulfonylureas and Related Compounds
2.2. Benzoic Acid Derivatives
2.3. Amino Acid Derivatives
2.4. Mode of Action
2.5. New Insulinotropic Mechanisms
2.5.1. Dipeptidyl Peptidase IV Inhibition
2.5.2. Dipeptidyl Peptidase IV Inhibitors in Clinical Development
3. Biguanides
4. Inhibitors of Intestinal Carbohydrate Digestion
4.1. α-Glucosidase Inhibitors
4.1.1. Mode of Action
4.1.2. Pharmacology
4.1.3. Individual Compounds
4.2. Plant Fibers
5. Enhancers of Insulin Action
5.1. Mode of Action
5.2. Pharmacology of PPAR γ agonists
5.3. Thiazolidine-2,4-Dione Derivatives (Glitazones)

The review describes all oral drugs used for the treatment of type 2 diabetes mellitus which are marketed or in late clinical development. Stimulators of insulin secretion are the most prescribed class of antidiabetic drugs. These compounds increase insulin secretion from pancreatic β-cells via the closure of the ATP-sensitive K^+ channel. Sulfonylurea (SU) derivatives bind to the SU receptor on a regulatory protein of the ATP-sensitive K^+ channel. Since various binding sites exist, also other compounds like benzoic acid or amino acid derivatives are able to bind and to stimulate insulin secretion via the closure of the ATP-sensitive K+ channel. Very new mechanisms, not yet approved and still in late clinical development, prevent the degradation of glucagons-like-peptide-1 (GLP-1), an intestinal hormone, which stimulates insulin secretion by increasing intracellular cAMP levels of β-cells. Those compounds, which inhibit the GLP-1 degrading enzyme dipeptidyl peptidase IV (DPP IV), sustain the insulinotropic effect of GLP-1. The antidiabetic action of biguanides, only metformin is marketed today, is still not fully understood. Metformin improves insulin sensitivity probably by an increase in peripheral glucose utilization and additionally metformin reduces hepatic gluconeogenesis. Alpha-glucosidase inhibitors are enzyme inhibitors of small intestinal carbohydrate digesting glucosidases. They display their antidiabetic effect by delaying the postprandial (pp) carbohydrate absorption resulting in reduced pp hyperglycemia and -insulinemia, which finally improves insulin sensitivity. Enhancers of insulin action are ligands of the peroxisome proliferator activated receptor γ (PPAR γ). PPARs belong to the nuclear receptor family of ligand-activated transcription factors. The major antidiabetic and blood glucose lowering effect of the PPAR γ agonists is the improvement of insulin sensitivity, however, the mechanism is not fully elucidated yet.

1. Introduction

Type 2 diabetes or noninsulin dependent diabetes mellitus (NIDDM) is a chronic disease of impaired carbohydrate, lipid, and protein metabolism, resulting from inadequate insulin action. Patients may have diminished insulin secretion, i.e., insulin deficiency, or insulin is secreted but does not act properly because of impaired sensitivity of muscle and liver to insulin (insulin resistance) [1], [2]. The treatment with antidiabetic drugs is aimed at achieving glycemic control to prevent the development of diabetic complications: neuropathy, nephropathy, and retinopathy. Oral antidiabetic drugs reduce or normalize elevated concentrations of glucose in blood and urine. Antidiabetic drugs available today aim at various target tissues and can be characterized by their different mode of actions. Basically two major pharmacological principles can be distinguished: (1) stimulation of insulin secretion (A) and (2) mechanisms where no elevated plasma insulin levels are required for glycemic control (B – D):

A. Insulin secretagogues act on the β-cells of the pancreas and stimulate insulin secretion.
B. Biguanides affect the glucose metabolism in the liver and peripheral tissues (e.g., skeletal muscle).
C. Inhibitors of carbohydrate digestion are active in the small intestine and delay carbohydrate digestion and glucose absorption.
D. Insulin sensitizers primarily act on peripheral tissues and enhance insulin action.

2. Stimulators of Insulin Secretion

2.1. Sulfonylureas and Related Compounds

When testing sulfonamide derivatives for antibacterial activity LOUBATIERES recognized their blood glucose lowering potential already in 1944 [3]. However, it took more than 10 years before the first non-antibacterial compounds carbutamide (Boehringer Mannheim) [4] and tolbutamide (Hoechst) [5] (Table 1) were introduced into the market for the treatment of type 2 diabetic patients in 1956.

Sulfonylurea (SU) derivatives of the first generation were active only in high dosages of up to 2000 mg/d. Sulfonylureas of the “second generation” showed much higher pharmacological potency and were active in significantly lower doses [6]. The first one, glibenclamide (glyburide) (Table 1), was introduced in the market by Boehringer Mannheim and Hoechst in 1969 requiring daily doses of only 2.5 – 15 mg.

Although the efforts in pharmaceutical sulfonylurea research decreased in the 1970s, investigations in the last two decades have been concentrated on increasing, prolonging, or shortening the action of insulin secretagogues or accelerating their onset of action. Glimepiride (Table 1), a structure closely related to glibenclamide in which the phenyl substituent of glibenclamide is replaced by pyrroline, was introduced into the market in 1996. In contrast to glibenclamide, in several animal species glimepiride is characterized by a faster onset of blood glucose lowering activity, and a longer-lasting glucose lowering effect [7].

Also in clinical trials, glimepiride showed longer-lasting hypoglycemic effects than glibenclamide [8]. Due to these properties, glimepiride was introduced as a drug for once-daily treatment. Although all 14 SU compounds of Table 1 are available at least in parts of the world, more than 90 % of the SU world market is dominated by only five SU derivatives — glibenclamide/glyburide, gliclazide, glipizide, chlorpropamide, and glimepiride (Table 1).

Table 1. Examples of insulin secretion simulators (daily dose for humans and threshold dose for rabbits) and elimination half life $\tau_{1/2}$

Generic name *M_r, mp,* Ref.	Examples of commercial preparations formula	Daily dose, mg	Threshold dose, mg	$\tau_{1/2}$ h

2.2. Benzoic Acid Derivatives

Research on the structure-activity relationship of potent “second generation” SUs like gliblenclamide has revealed that the nonsulfonylurea moiety of glibenclamide also stimulated insulin secretion. The benzoic acid derivative meglitinide (HB 699) stimulated insulin release in vitro and in vivo, but the potency was only comparable to tolbutamide [8]. Repaglinide, the active (S)-enantiomer of AG-EE 388 ZW (Boehringer Ingelheim) (Table 1) is a benzoic acid derivative with remarkably higher potency, comparable with glibenclamide [23]. Due to its different pharmacokinetic behavior from glibenclamide, more rapid absorption, and shorter half-life, repaglinide showed interesting pharmacological properties in terms of quick insulin release and short-acting blood glucose lowering effects [24]. Repaglinide was introduced into the market in 1998.

2.3. Amino Acid Derivatives

Amino acid derivatives derived from D-phenylalanine are structurally a new type of insulin secretagogues [23].

Nateglinide (A-4166), Starlix, shows stereospecific activity, and it was found that the R-configuration was essential for hypoglycemic activity.

It is suggested that the phenylmethyl substituent of the amino acid residue is essential for activity. Variation of the amino acid moeity, e.g., glycine, alanine, phenylglycine, tyrosine, and others reduced the hypoglycemic activity [23]. Nateglinide produces a very quick insulin release followed by a rapid onset of blood glucose decrease and shows a short duration of action [25], [26]. Clinical trials have demonstrated mild blood glucose lowering activity after single doses of 60 – 180 mg. The first market introduction was in 1999 in Japan and in 2001 in USA.

Mitiglinide [145525-41-3] (KAD-1229, Kissei Pharmaceutical) is another non-sulfonylurea insulin secretagogue [27]. Mitiglinide is a benzylsuccinic acid derivative and in phase III of clinical development.

2.4. Mode of Action

Insulin secretion is physiologically stimulated by the binding of ATP to a cytosolic nucleotide binding site of the membrane bound ATP-sensitive K^+ channel which leads to closure of the K^+ channel. The inhibition of K^+ permeability depolarizes the plasma membrane, subsequently the voltage-dependent Ca^{2+} channel opens to promote the Ca^{2+} influx which finally results in insulin secretion [28].

The insulin secretagogues stimulate insulin secretion by closure of this ATP-sensitive K^+ channel of pancreatic β-cells. The KATP-channel consists of two subunits, a functional ion channel pore and a regulatory protein. The binding of the secretagogues is suggested to occur to the separate regulator protein containing the binding sites for sulfonylureas (sulfonylurea receptor 1, SUR1) but also other compounds [26], [27], [29].

2.5. New Insulinotropic Mechanisms

In 2005, a new antidiabetic principle was approved in the USA and introduced in the market: exendin-4 (Exenatide) [30], [31], an injectable analogue of the gastrointestinal peptide hormone glucagon-like peptide-1 (GLP-1) (see ⟶ Peptide and Protein Hormones). GLP-1 stimulates insulin secretion in a glucose-dependent manner with little risk of hypoglycemia via activation of the β-cell hormone receptor. Additionally, GLP-1 shows further important effects on β-cells, insulin biosynthesis and glucagon secretion, as well as on gastric motility. However, GLP-1 is unsuitable as a therapeutic agent, because of rapid enzymatic degradation by dipeptidyl peptidase IV (DPP IV also known as CD26) which results in a half-life of about two minutes [32].

2.5.1. *Dipeptidyl Peptidase IV Inhibition*

Very shortly after the discovery in 1993 that DPP IV inactivates GLP-1 [33], the inhibition of DPP IV was proposed as a new antidiabetic therapy using the attractive antidiabetic profile of GLP-1 [34]. Differently from injectable peptide hormones, all DPP IV inhibitors under development are orally available drugs.

DPP IV inhibitors sustain the plasma concentrations of GLP-1 by preventing the N-terminal degradation of GLP-1 [35], which results in significant enhancement of its insulinotropic activity, as well as improvement of islet function, which has been observed in long-term animal studies with DPP IV inhibitors [36], [37].

In general, good tolerability has been reported for DPP IV inhibitors in clinical studies. However, little data are available with respect to selectivity regarding other DPPs (e.g., DPP 8/9) [38], [39] and consequences of their inhibition are unknown. And because DPP IV cleaves and inactivates a variety of peptide hormones, special observation in long-term trials is needed for the safety evaluation of this class of drugs.

2.5.2. *Dipeptidyl Peptidase IV Inhibitors in Clinical Development*

The most advanced compounds in clinical phase III trials are vildagliptin [274901-16-5] (LAF-237, Novartis) [40]

and *sitagliptin* [274901-16-5] (MK-0431, Merck & Co.) [41].

The only published long-term (52 weeks) trial results are available for vildagliptin (50 mg OD) in combination with metformin. Vildagliptin showed reductions in HbA_{1C} after 12 weeks (Δ = –0.7 %) and good tolerability after 52 weeks [42]. Further long-term clinical trials with both, vildagliptin and sitagliptin, are still ongoing. Although no long-term data are published with sitagliptin, in USA a new drug approval (NDA) for sitagliptin was filed in early 2006. It is too early for an evaluation of the

therapeutic efficacy, but in general, one may say DPP IV inhibitors reduce glycemia and glucagon levels, sustain insulin levels in patients, improve the glucose tolerance and as a glucose-dependent insulin secretagogue they avoid serious hypoglycemic events [43], [44].

[Top of Page]

3. Biguanides

The hypoglycemic activity of guanidine derivatives was firstly reported in 1918 [45]. The first blood glucose lowering diguanidine derivative decamethylenediguanidine (Synthalin A) was synthetized in the 1920s. Because of liver toxicity development of these compounds was discontinued. Only in the 1950s three biguanides were developed. The disubstituted dimethylbiguanide metformin [657-24-9] was introduced in 1957.

Monosubstituted compounds with a longer side chain, the phenylethylbiguanide *phenformin* [114-86-3] and the *N*-butylbiguanide *buformin* [692-13-7], were introduced in the same year and 1958, respectively [46].

Pharmacology and Mode of Action. Biguanides are ineffective in normal animals, unless very high doses are used and there is no risk of hypoglycemia. However, in diabetic animals blood glucose-lowering effects of biguanide can be demonstrated, depending on the model used. Biguanides do not stimulate insulin secretion, but need insulin for pharmacological hypoglycemic activity. In severe insulinopenic animal models, high doses have to be used and effects are modest. In mild diabetic animals or in insulin resistant animals, lower doses are already efficacious in lowering hyperglycemia and hyperinsulinemia [47].

The mechanism of action of biguanides is still not fully understood. Three major tissues have been identified as pharmacological sites of action: (1) the small intestinal wall, (2) the liver, and (3) peripheral tissues, mainly the skeletal muscle:

1. For the small intestine an inhibition of glucose absorption was described, however, this is, at least for metformin, of minor significance and not important for the blood glucose lowering effect. However, the intestinal glucose metabolization to lactate is stimulated and reduces the postprandial uptake of glucose by the liver.
2. Numerous studies have shown that biguanides inhibit hepatic gluconeogenesis and this may contribute to the blood glucose lowering effect, particularly in the fasting state. Again, metformin has probably less impact on gluconeogenesis than phenformin and buformin.
3. In the peripheral tissues, metformin increases the glucose disposal and utilization particularly in the skeletal muscle, which is probably the major contribution to the blood glucose lowering activity. In vitro studies using cell cultures have shown that metformin potentiates insulin action. In vivo studies in animals and diabetic patients have demonstrated that metformin reduces insulin resistance, at least in obese individuals [47], [48].
   Phenformin and buformin may cause lactic acidosis, which is the most serious adverse event of biguanides. Due to very serious cases of lactic acidosis both drugs were withdrawn from the markets in most parts of the world during the 1970s. Today they are available only in a few countries of Eastern Europe and South America. Owing to a more favorable pharmacokinetic profile of metformin, metformin associated lactic acidosis is very rare [48]. Therefore, only metformin is available today in all important countries. In the 1990s metformin experienced a renaissance in many countries, particularly in the USA, where metformin was approved for the treatment of type 2 diabetes only in 1994.

[Top of Page]

4. Inhibitors of Intestinal Carbohydrate Digestion

Delaying absorption as a therapeutic principle is well accepted for dietary therapy to avoid high postprandial blood glucose excursions [49]. Carbohydrates represent quantitatively the major portion of the human diet, in the form of mono-, di- and polysaccharides. However, only the relatively infrequently occurring monosaccharides such as glucose and fructose can be absorbed and are readily taken up from the small intestine. The more important dietary carbohydrate components, the complex starches and also sucrose have to be hydrolyzed enzymatically to their constituting monosaccharides by specific intestinal α-glucosidases (α-amylase, glucoamylase, dextrinase, maltase, isomaltase and sucrase) before they can be absorbed. The high density of intestinal membrane bound α-glucosidase enzymes in the jejunum and the high proportion of refined carbohydrates in the Western diet are the main reasons that the digestive process usually takes place very rapidly in the proximal small intestine. As a result, a high carbohydrate digestion rate leads to a rapid postprandial rise in blood glucose which is followed by a glucose stimulated insulin increase [50].

4.1. α-Glucosidase Inhibitors

α-Glucosidase inhibitors are of various chemical structures (polypeptides and carbohydrates). The most potent inhibitors are from a carbohydrate-derived backbone containing a nitrogen atom in the molecule. Polypeptides are less active.

4.1.1. *Mode of Action*

Essential for the action of the carbohydrate-type α-glucosidase inhibitors is their intramolecular nitrogen atom, which binds to the carbohydrate binding site of the intestinal α-glucosidases [51]. Compared with the oxygen atom of the α-glycosidic bond of dietary complex carbohydrates, the affinity of the nitrogen atom to the carbohydrate binding site of the enzyme is much

higher (factor 10^4 – 10^7). Despite their high affinity for these enzymes, the binding of α-glucosidase inhibitors is reversible and their inhibition kinetics are competitive [52].

4.1.2. *Pharmacology*

Pharmacological inhibition of intestinal α-glucosidases effectively retards the digestion of carbohydrates, slows down the absorption of glucose and avoids the often very high postprandial blood glucose peaks particularly in diabetic patients. As a result the postprandial glycemia and glucose stimulated hyperinsulinemia are flattened and the metabolic control will be improved. From the primary pharmacological effects, it can be concluded that α-glucosidase inhibitors act to reduce postprandial hyperglycemia without stimulating insulin secretion, thus avoiding any risk of hypoglycemia. Because of their unique mode of action in the small intestine, α-glucosidase inhibitors can be used in combination with all other antidiabetic treatments and act in an additive manner together with other antidiabetic drugs [50].

4.1.3. *Individual Compounds*

The first active compounds were inhibitors of the *soluble pancreatic α-amylase*. BAY D 7791 was a protein isolated from wheat flour [53]. This α-*amylase* inhibitor inhibited the postprandial blood glucose rise in oral loading tests with raw starch, but was much less effective when used together with cooked starch.

BAY E 4609, an α-amylase inhibitor of microbial origin, was characterized to be of carbohydrate nature and showed a significantly higher inhibitory potency [53]. However, also this compound demonstrated only modest efficacy in clinical trials. Because α-amylase inhibitors affect only starch digestion, the degradation of important oligo- and disaccharides by the membrane bound enzymes is not inhibited, the overall efficacy is only modest.

Further research aimed at inhibitors of the membrane bound α-*glucosidases*. This approach was very successful and lead to the discovery of acarbose (Table 2) [54], the first α-glucosidase inhibitor, which was introduced into the market for the treatment of type 2 diabetic patients in 1990 (in many countries also for type 1 in addition to insulin).

Table 2. α-Glucosidase inhibitors

Generic name M_r, *mp*, Ref.	Examples of commercial preparations formula	Daily dose
Acarbose [56180-94-0] $C_{25}H_{43}NO_{18}$	Glucobay, Precose, Prandase, Glucor (Bayer)	100 – 300 mg
		
645.61; amorph [55] *O*-{4,6-Dideoxy-4-[1(*S*)-(1,4,6/5)-4,5,6-trihydroxy-3-hydroxymethyl-2-cyclohexene-1-yl]amino- α-D-glucopyranosyl}-(1 ⟶ 4)-*O*- α-D-glucopyranosyl-(1 ⟶ 4)-D-glucose		
Miglitol [72432-03-2] $C_8H_{17}NO_5$	Diastabol (Sanofi) Glyset (Pfizer) Seibule (Sanwa Kagaku)	50 – 300 mg
		
207.23; 114 °		

C [56] 1,5-Dideoxy-1,5-[(2-hydroxyethyl)imino]-D-glucitol		
Voglibose [83480-29-9] $C_{10}H_{21}NO_7$	Basen (Takeda)	0.3 – 0.9 mg
		
267.28; 162 – 163 °C [57] 3,4-Dideoxy-4-[[2-hydroxy-1-(hydroxymethyl)ethyl]amino]-2-*C*-(hydroxy-methyl)-D-epiinositol		

Acarbose is a pseudotetrasaccharide of microbial origin, and was isolated from bacterial culture broths (*Actinoplanes* spec.) by Bayer [51], [52]. Acarbose consists of an acarviosine unit and maltose. The acarviosine nitrogen is responsible for the high affinity to the active binding site of α-glucosidases, however, the C – N linkage cannot be hydrolyzed and the enzymatic reaction stops.

Further research generated smaller molecules with different structures. The synthetic N-substituted valiolamine and the N-substituted 1-deoxynojirimycin derivatives showed even higher affinity to various α-glucosidases [51], [53].

The 1-deoxynojirimycin derivative *miglitol* (BAY M 1099) (Table 2) shows similar activity to acarbose with daily dosages of 50 – 300 mg [52].

Emiglitate (BAY O 1248) [80879-63-6], another deoxynojirimycin analogue is characterized by at least five-fold higher inhibitory potency than acarbose and additionally shows a long-lasting inhibitory effect [51], [52].

In animal studies emiglitate was still active up to 17 h after a single oral administration due to its pharmacokinetic behavior (formation of an active metabolite) [53], [58]. Both miglitol and emiglitate differ in their pharmacokinetic behavior from acarbose, which is poorly absorbed (1 – 2 %). The deoxynojirimycin derivatives are structurally related to monosaccharides and will be absorbed in the jejunum [58].

The most potent α-glucosidase inhibitor is the valiolamine derivative *voglibose* (Takeda) (Table 2). Compared with acarbose its inhibitory potency in vitro, depending on the α-glucosidase enzyme, is up to 200 times higher [51], [53]. In Japan, daily dosages are only 0.3 – 0.9 mg, however, therapeutic efficacy on HbA1c reduction could not be clearly demonstrated with those dosages. HbA1c, a glycated hemoglobin species, which occurs in blood, is a diagnostic measure for the non-enzymatic glycation process, and depends on the plasma glucose concentration. The process of protein glycation is discussed to be responsible for the development of diabetic complications (neuropathy, retinopathy, nephropathy). In Europe voglibose is under evaluation with distinctly higher daily dosages of 1.5 to 6 mg [59]. In contrast to acarbose, the smaller inhibitors of the monosaccharide type (miglitol, emiglitate, voglibose) do not inhibit pancreatic α-amylase [51], [53].

4.2. Plant Fibers

A more dietary approach for delaying absorption of nutrients is the use of undigestable carbohydrate polymers. Guar gum [9000-30-0] is a galactomannan obtained from the seeds of the guar plant (*Cyamopsis tetragonoloba*). Guar gum has no specific pharmacological site of action, but delays the absorption of digestible carbohydrates because it increases the viscosity in the small intestine and additionally hinders physically the enzymatic degradation of digestible carbohydrates. This approach is less effective in delaying the carbohydrate absorption than the pharmacological approach by the use of α-glucosidase inhibitors.

[Top of Page]

5. Enhancers of Insulin Action

The thiazolidine-2,4-dione derivatives (TZDs or glitazones) are insulin sensitizing compounds which improve glucose utilization without stimulating pancreatic insulin secretion. However, the thiazolidinediones are only active in conjunction with

insulin and show the best results in hyperinsulinemic, insulin resistant, obese individuals (animals and humans). The first compound *ciglitazone*, synthetized by Takeda and reported in 1982, was a result of screening of clofibrate analogues for hypolipidemic activity [60], [61].

5.1. Mode of Action

The mechanism of blood glucose lowering activity by thiazolidinedione derivatives has not been fully elucidated yet. Only minor or no effects are observed in normal animals or insulin sensitive diabetes models. In obese or hyperinsulinemic insulin resistant rodents thiazolidinediones lower insulin and triglyceride levels after treatment for 2 to 8 d. If hyperglycemia occurs, also the blood glucose concentration is reduced [23], [61].

Mechanistic in vitro studies with adipocytes have shown that the thiazolidinediones are ligands of the peroxisome proliferator activated receptor γ [62]. Peroxisome proliferator activated receptors (PPARs) belong to the nuclear receptor superfamily of ligand-activated transcription factors.

So far, three receptor subtypes have been identified: PPAR α, PPAR δ, and PPAR γ. The PPARs are believed to play a physiological role in the regulation of lipid metabolism [63], [64]. The in vivo antihyperglycemic activity of thiazolidinediones strongly correlates with their potency as PPAR γ agonists in vitro [65]. The mechanisms responsible for the blood glucose effects are controversally discussed, however, as long as there are no more mechanistic data available it is suggested that PPAR γ is a primary site of action of the thiazolidinediones [66].

5.2. Pharmacology of PPAR γ agonists

Ciglitazone reduced plasma triglycerides, hyperglycemia and hyperinsulinemia in several insulin resistant diabetic and non-diabetic rodent models after repeated oral dosing at doses of 100 – 300 mg/kg body weight, while having little or no effect in normal rodents or those with insulin deficient diabetes [61]. In long-term animal studies lens cataracts occurred and ciglitazone development was discontinued. Further synthetic research on thiazolidinedione analogues yielded compounds of distinctly higher in vitro and in vivo activity. Depending on the animal model, after repeated dosing troglitazone lowered hyperglycemia as well as levels of free fatty acids, triglycerides, and insulin at daily doses of 50 mg/kg p.o. or slightly lower [23], [67]. The glitazones are not only able to reduce insulin resistance, in vitro and in vivo studies have demonstrated increased synthesis of glucose transporter 1 (GLUT1) in various tissues. Little or no effect was observed on the insulin sensitive glucose transporter 4 (GLUT4), synthesis or insulin stimulated translocation of GLUT4, particularly in adipocytes, were only slightly increased. These effects may contribute to increased cellular glucose uptake [68].

In accordance with the PPAR γ mechanism, which primarily affects the adipose tissue, all obese animals gain weight under treatment with glitazones [64].

5.3. Thiazolidine-2,4-Dione Derivatives (Glitazones)

Clinical trials have confirmed the preclinical results. Best effects were observed in obese, highly insulin resistant type 2 diabetic patients and particularly in combination with insulin secretagogues (SU). However, the increase in body weight gain was also observed [64].

Troglitazone (Sankyo, see Table 3) was firstly approved 1995 in Japan and 1997 in USA and UK. It was launched in these countries in 1997. The recommended starting dose was 400 mg/d and the highest dose 600 mg. After being marketed, the daily practice revealed adverse events in the liver with cases of fatal liver failure. This lead to withdrawal of troglitazone from the market in the UK already after two months [69], in USA and Japan in the year 2000 [70].

Table 3. Thiazolidine-2.4-dione derivatives (TZDs)

Generic name M_r, *mp,* Ref.	Examples of commercial preparations formula	Daily dose
Pioglitazone [112529-15-4] $C_{19}H_{20}N_2O_3S \cdot HCl$	Actos (Ely Lilly) (Takeda)	15 – 45 mg
392.90; 183 – 184 °C [72] (±)-5-[[4-[2-(5-Ethyl-2-pyridinyl)ethoxy]phenyl]methyl]-2,4-thiazolidinedione, hydrochloride		
Rosiglitazone [122320-73-4] $C_{18}H_{19}N_3O_3S$	Avandia (SKB)	4 – 8 mg

357.43; 122 – 123 °C

[73]

5-(4-[2-(Methylpyridin-2-ylamino)ethoxy]benzyl)thiazolidine-2,4-dione

Troglitazone [97322-87-7] Noscal (Sankyo) Rezulin (Warner-Lambert) 400 – 600 mg

$C_{24}H_{27}NO_5S$

441.55; 184 – 186 °C

[74]

5-[[4-[(3,4-Dihydro-6-hydroxy-2,5,7,8-tetramethyl-2*H*-1-benzopyran-2-yl) methoxy]phenyl]methyl]-2,4-thiazolidinedione

---

Pioglitazone (Table 3) is approximately ten times more potent in both, animals, and humans than troglitazone. The highest potency shows *rosiglitazone* (Table 3), which is approximately 100-fold more active than troglitazone [69]. Both compounds showed better tolerability in clinical trials than troglitazone. Both drugs were introduced into the US market in 1999, and differently from troglitazone, for these TZDs, hepatotoxicity is less serious. However, both drugs cause fluid retention, therefore, heart failure could be a potential risk for special patients [71].

4. **Metoclopramide** 3
5. **References** 3

Nausea and vomiting (emesis) can be induced by certain types of drugs (emetics) or in most persons by motion (motion sickness). Nausea and vomiting can result from surgery, irradiation, cancer chemotherapy, pregnancy, and gastrointestinal disorders.

Emetics are drugs that induce vomiting. They are used only on orally intoxicated patients who for some reason cannot undergo lavage, a much safer method of emptying the stomach. However, even in such cases emetics have limited value because of their side effects. The most widely used emetic is apomorphine hydrochloride [*41372-20-7*], $C_{17}H_{18}ClNO_2$, M_r 303.79, which induces vomiting within a few minutes of subcutaneous injection. The usual dose is 5 mg.

Apomorphine hydrochloride

Antiemetics are drugs that suppress nausea and vomiting. In many cases their mechanism of action is not fully understood. Generally antiemesis results from direct suppression of the chemoreceptor trigger zone, by action on the vestibular apparatus, or by local or central effects. The most widely used antiemetics are tropane alkaloids, benzhydryl derivatives, and phenothiazines.

1. Tropane Alkaloids

Tropane alkaloids were the first drugs used to prevent motion sickness.

Scopolamine [*51-34-3*] and L-hyoscyamine [*101-31-5*] are the most commonly used alkaloids (→ Alkaloids, Chap. 4.). A prophylactic dose of 0.1 mg scopolamine hydrobromide protects against the symptoms of motion sickness in 75 % of all cases. Side effects are rare at this dosage. Intramuscular injection of 0.2 mg can relieve motion sickness symptoms. L-Hyoscyamine acts in a similar way but is less potent.

2. Benzhydryl Derivatives

Chlorphenoxamine [*77-38-3*], 2-[1-(4-chlorophenyl)−1-phenylethoxy]-*N*,*N*-dimethylethyl-amine, $C_{18}H_{22}ClNO$, M_r 303.84, *bp* 150 – 155 °C (7 Pa). The hydrochloride [*562-09-4*], $C_{18}H_{23}Cl_2NO$, M_r 340.30, *mp* 128 °C, is soluble in water.

Chlorphenoxamine is prepared by action of methylmagnesium chloride on 4-chlorobenzophenone and subsequent alkylation of the carbinol with *N*,*N*-dimethyl-2-chloroethylamine [1].

Chlorphenoxamine is also used in combination with 8-chlorotheophylline.

Trade names: Rodavan (Asta), Phenoxene (Dow).

Cyclizine [*82-92-8*], 1-(diphenylmethyl)−4-methylpiperazine, $C_{18}H_{22}N_2$, M_r266.39, *mp* 106 °C, is soluble in ethanol and chloroform and partly soluble in water. The hydrochloride [*303-25-3*], $C_{18}H_{23}ClN_2$, M_r 302.85, *mp*

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a03_009

285 °C (decomp.), is moderately soluble in water. The lactate [*5897-19-8*], $C_{21}H_{28}N_2O_3$, M_r 356.47, is suitable for intramuscular injection.

Synthesis: alkylation of *N*-methylpiperazine with benzhydryl chloride [2].

Trade names: Collox (Wellcome), Marezine (Wellcome).

Diphenhydramine [*58-73-1*], 2-diphenylmethoxy-*N*,*N*-dimethylethylamine, $C_{17}H_{21}NO$, M_r 255.53, *bp* 150 – 165 °C (0.270 kPa); hydrochloride [*147-24-0*], $C_{17}H_{22}ClNO$, M_r 291.82, *mp* 166 – 170 °C. One gram of diphenhydramine is soluble in 1 mL of water, 2 mL of ethanol, 2 mL of chloroform, or 50 mL of acetone; the compound is very slightly soluble in benzene or ether.

Synthesis: diphenylmethyl bromide, *N, N*dimethylaminoethanol, and sodium carbonate are heated in toluene [3].

Trade name: Benadryl (Parke-Davis).

As an antiemetic diphenhydramine is used most widely as the 8-chlorotheophyllinate: *Dimenhydrinate*
[*523-87-5*], $C_{17}H_{21}NO \cdot C_7H_7ClN_4O_2$, M_r 469.96, *mp* 102 – 107 °C, which is freely soluble in ethanol and chloroform, slightly soluble in water, and almost in-soluble in ether.

Dimenhydrinate is prepared by heating the components (1 : 1 mixture) in ethanol [4].

Trade names: Vomex (Endopharm), Dramamine (Searle).

Diphenidole [*972-02-1*], 1,1-diphenyl-4-piperidinobutanol, $C_{21}H_{27}NO$, M_r 309.43, *mp* 104 – 105 °C. The hydrochloride [*3254-89-5*], $C_{21}H_{28}ClNO$, M_r 345.91, is used for tablets and injections.

Diphenidole is prepared by reacting the Grignard reagent of 1-(3-chloropropyl)piperidine with benzophenone in tetrahydrofuran. The crude product is recrystallized from 2-propanol [5].

Trade names: Vontrol (Smith Kline & French), Cephadol (Nippon Shinyaku).

Meclozine [*569-65-3*], 1-[(4-chlorophenyl)-phenylmethyl]−4-[(3-methylphenyl)methyl]-piperazine, $C_{25}H_{27}ClN_2$, M_r 390.96, *bp* 230 °C (270 Pa). The dihydrochloride [*1104-22-9*], $C_{25}H_{29}Cl_3N_2$, M_r 463.90, *mp* 224 °C (decomp.), is readily soluble in chloroform and pyridine, slightly soluble in dilute acids and ethanol, and insoluble in water or ether.

Meclozine is prepared by alkylation of (3-methylbenzyl)piperazine with 4-chlorobenzhydrylchloride [6].

Trade names: Antivert (Roerig), Bonamine (Pfizer).

3. Phenothiazine Derivatives

Many phenothiazines are antiemetics as well as neuroleptics (→ Phenothiazine and Derivatives).

Prochlorperazine [*58-38-8*], 2-chloro-10-[3- (4-methyl-1-piperazinyl)-propyl]−10*H*-pheno-thiazine (**1**, X = Cl), $C_{20}H_{24}ClN_3S$, M_r 373.94, *mp* 228 °C; for synthesis → Phenothiazine and Derivatives.

1

Usually the free base is administered rectally. The *ethanedisulfonate* of prochlorperazine [*1257-78-9*], $C_{22}H_{30}ClN_3O_6S_3$, M_r 564.13, and the dimaleate [*84-02-6*], $C_{28}H_{32}ClN_3O_8S$, M_r606.09, are used as oral antiemetics.

Trade name: Compazine (Smith Kline & French).

Thiethylperazine [*1420-55-9*], 2-ethylthio-10- [3-(4-methyl-1-piperazinyl)propyl]−10*H*-phenothiazine (**1**, X = SC_2H_5), $C_{22}H_{29}N_3S_2$, M_r 399.61, *bp* 227 °C (1 Pa), acts both as a peripheral and as a central antiemetic. The malate [*52239-63-1*], $C_{30}H_{41}N_3O_{10}S_2$, M_r 667.79, is suitable for intramuscular injection, whereas the maleate [*1179-69-7*], $C_{30}H_{37}N_3O_8S_2$, M_r 631.76 is an oral antiemetic.

Trade name: Torecan (Boehringer Ingelheim).

Trifluopromazine [*146-54-3*], 10-[3-(4-methyl-1-piperazinyl)-propyl]−2-trifluoromethyl-10*H*-phenothiazine (**1**, X = CF_3), $C_{21}H_{24}F_3N_3S$, M_r 407.49, *bp* 202 – 210 °C (80 Pa), is an oral antiemetic. For its preparation → Phenothiazine and Derivatives.

Trade name: Psyquil (Heyden).

Other phenothiazine derivatives that have their chief use as tranquilizers and neuroleptics are used as antiemetics occasionally: chlorpromazine, hydroxyzine, and haloperidole.

4. Metoclopramide

Metoclopramide [*364-62-5*], $C_{14}H_{22}ClN_3O_2$, M_r 299.81, is the most important antiemetic in Japan.

Metoclopramide is prepared by the reaction of *N,N*-diethylethylenediamine with 4-acetamido-5-chloro-2-methoxybenzoyl chloride [7].

Trade names: Cerucal (VEB Arzneimittelwerk), Maltyl (Diabetylinges.), Maxolon (Beecham), Metoclol (Toyama), Moriperan (Morishita), Peraprin (Taiyo), Pramiel (Teisan), Reliveran (Finadiet).

Monohydrochloride monohydrate [*54143-57-6*], $C_{14}H_{23}Cl_2N_2O_3$, M_r 338.26, *mp* 182.5 – 184 °C, is a colorless powder, soluble in water.

Trade names: Eucil (Farmasa), Maxeran (Nordic), Paspertin (Kali-Chemie), Plasil (Lepetit), Reglan (Robins).

Dihydrochloride monohydrate [*2576-84-3*], $C_{14}H_{24}Cl_3N_3O_2$, M_r 374.72, *mp* 145 °C (decomp.), is soluble in water and methanol and partially soluble in ethanol.

Trade names: Gastronerton (Dolorgiet), Imperan (Delagrange, Bender), Primperan (Fujisawa Yakuhin).

1. Introduction

Epilepsy is a condition of recurrent, paroxysmal seizures. The epileptic seizure represents an abnormal synchronized discharge among a large population of central neurons. Depending on the neuronal populations involved, a disturbance of movement, sensation, behavior, or consciousness can result from the discharges [1]. However, a seizure can only be seen as a symptom which principally can be induced in every individual if strong enough stimulation is applied. Epilepsy is characterized by the increased susceptibility to experience seizures upon exogenous or endogenous stimuli. Clinically, only a patient who has experienced three or more seizures is considered to be epileptic [2].

About 0.5 – 1 % of the world's population (i.e., more than 50×10^6 people) suffer from epilepsy, which makes it one of the most common neurological disorders; no major difference is found between developed and developing countries [3]. The disease usually starts in childhood with a second peak in elderly people, but people can become epileptic at any age. Once acquired, patients usually suffer from the disease throughout their lives [3].

The diagnosis of epilepsy is based on clinical observations of the seizures and on recording of changes in the electrical activity of the brain using scalp electrodes (electroencephalography, EEG). Since patients in most cases lose consciousness during seizures and since EEG recordings between seizures can be fully normal, a preliminary diagnosis is often based on seizure descriptions obtained from eye witnesses. Ancillary investigations exploring the etiology of the condition include different imaging techniques, seizure provocation experiments, and depth electrode recordings. Epileptic seizures can be distinguished from other convulsive-like states not involving synchronous activation of neuronal cells. Examples of these states include transient ischemic attacks or hyperventilation resulting in loss of righting reflexes due to fainting.

The pathophysiology of epilepsy is diverse, involving both intrinsic and extrinsic factors. Developmental or congenital anomalies such as neuronal dysplasia, vascular malformations, and cerebral atrophy as well as cerebral tumors, meningitis, encephalitis or, cerebrovascular diseases are possible intrinsic factors. Birth trauma, head injuries, anoxic disturbances induced by respiratory arrest, intoxication with heavy metals or other toxins and endocrine disorders such as uremia, hypoglycemia, or hypocalcemia are exogenous factors [4]. However, in most patients the epilepsy is of idiopathic origin. The precise mechanism involved in the increased susceptibility to synchronized discharges is still unknown. However, based on experiments with anticonvulsant and proconvulsant drugs and on biochemical findings from human epileptic tissue, several theories have been proposed. The increased excitability could be related to both neurotransmitter and ion channel function. An overactive excitatory and a reduced inhibitory neurotransmitter system has been found in these tissues. Reported changes in ion channel func-

10.1002/14356007.a03_013

tion resulted in a diminished membrane potential and a defective repolarization of the action potential. Besides these functional results, several genetic changes have been reported in both epilepsy-prone animals and in subpopulations of humans with epilepsy leading to hereditary epileptic syndromes [5], [6].

1.1. Classification

Seizures are stereotyped within individuals, but vary considerably between patients. This necessitates a system of classification for both seizures (symptomatic classification) and epileptic syndromes (syndromatic classification). The most generally accepted classification system is that of the International League Against Epilepsy [7].

Classification of Seizures. Seizures are classified as to whether their onset is partial (focal) or generalized.

Partial seizures are further subdivided according to whether consciousness is retained throughout the seizure (simple partial seizures) or impaired at some point (complex partial seizures). Patients having *simple partial seizures* show jerks or convulsions on one extremity. During *complex partial* seizures, the patient is in a state of reduced consciousness, not fully recognizing his surroundings, experiencing hallucinations and performing automatic gestures, such as talking, fumbling with clothing, or walking around. Any partial seizure can become *secondarily generalized* into a tonic – clonic convulsion.

Generalized seizures are further subdivided according to whether only consciousness is lost (absence seizures) or muscle activity is involved (myoclonic, clonic, tonic, tonic – clonic, or atonic seizures). An *absence seizure* is characterized by a sudden interruption of consciousness lasting only a few seconds without any other symptoms or with only a quick jerk of the eyes or hands. *Myoclonic seizures* are characterized by sudden jerks on the musculature of the limbs, the head, or the whole body, appearing in connection with absence seizures or as a separate entity. During an *atonic seizure* patients exhibit a sudden loss of muscle tone resulting in a fall to the ground (drop attack). Consciousness may be lost but is immediately regained. *Tonic-clonic seizures* start with a sudden loss of consciousness and a fall to the ground; a few seconds of intense tonic spasms of major muscles are followed by generalized jerks of the whole body. These convulsions gradually cease, leaving the patient comatose and flaccid. A gradual recovery of consciousness follows, often combined with confusion and drowsiness. *Status epilepticus* is a condition in which seizures follow each other without a recovery of consciousness between them. Both absence seizures and convulsive seizures can occur as status epilepticus.

Classification of Syndromes. A classification of epileptic syndromes is based not only on seizure characteristics but on more general features of the disease such as age of onset, type of EEG abnormalities, associated neurological features, or possible cause of disease including genetic factors [8], [9]. The International League Against Epilepsy [7] has listed more than 30 different epileptic syndromes.

1.2. Treatment of Epilepsy

The treatment of epilepsy is based on pharmacotherapy to suppress the seizure attacks, behavioral therapy to avoid seizure initiating situations, and on surgical resection of the seizure focus. As yet no ideal and general treatment regime exists for epileptic patients; the therapy rather has to be adopted individually. With optimal usage of the aforementioned strategies, seizures can be fully controlled in about 70 – 80 % of patients, however, side effects often have to be accepted [10]. Although surgical resection of the hyperexcitable focus is considered the only available cure for epilepsy, only a small percentage of patients, i.e., those having a defined singular focus which can be resected without disturbing vital brain functions, is eligible for surgery. Based on this well-defined population, the success rate of surgery is high but serious side effects can occur such as unwanted changes in personality or loss of brain functions like short term memory or ability to speak [11]. Behavioral treatment is aimed at avoiding endogenous or exogenous stimuli and is therefore only of symptomatic nature. Generally, the same is also

true for pharmacotherapy, which is aimed at suppressing the seizure attacks. The pharmacotherapy must be adapted both to seizure type and epileptic syndrome.

Antiepileptics (anticonvulsants) can be divided into drugs active against generalized absence seizures, those against partial seizures, and in drugs with a broad spectrum of activity. As of 2000, a syndrome-related therapy is in its beginnings. Although for some syndromes a selective therapy exists, such strategy is still limited due to a lack of selective drugs for most syndromes. Since seizures are often resistant to pharmacotreatment, two or more anticonvulsant drugs are concomitantly administered to improve seizure control [2], [12].

1.3. Discovery Strategies for New Antiepileptic Drugs

Since the pathomechanisms of epilepsy are not fully understood, it is impossible to define a straightforward strategy to develop drugs aimed at a molecular target which is solely and critically involved in generation of seizures. Therefore, nonrational (older) strategies of drug development are still valid in this field [13], [14].

Serendipitous search for new drugs, based on anticonvulsant effects observed in in vivo or in vitro screening models of seizures, may lead to drugs with unknown modes of action but potent anticonvulsant activity. This approach, however, is limited by the animal models used [15]. If models are selected based on efficacy of known drugs, only drugs with a similar anticonvulsant profile might evolve. If models are selected to mimic the disease state or drug resistance [16], the predictive value might still be limited. A second possibility to find new marketable drugs is to optimize the structure of known anticonvulsants using predictive animal models and structure – activity relationship (SAR) modeling to improve anticonvulsant potency while reducing unwanted effects or to optimize the physicochemical behavior. This approach is hampered by the same restrictions as the first one, since it is also based on experimental model results.

Although a rational approach may be limited, the knowledge of mechanisms of action of anticonvulsant drugs and of possible pathomechanisms involved in epilepsy can generate several approaches. A straightforward possibility is to investigate the mechanisms of action of currently known antiepileptic drugs. Such an approach will lead to drug discovery targets which are not necessarily involved in epilepsy but in antiepileptic drug action. Examples of drugs are use-dependent sodium channel blockers, T-type calcium channel blockers, and drugs enhancing γ-aminobutyric acid (GABA) ergic or reducing excitatory glutamatergic neurotransmission. However, the resulting new drugs may not differ in therapeutic potential from the old ones.

Another approach is to investigate human tissue resected from epileptic foci during surgery or to analyze the genom of patients with hereditary epileptic syndromes to track down the mutated gene and consequently the misfunctional protein. In epileptic tissue, levels of neurotransmitters, densities of receptors, or gene expression levels can be compared with those in nonepileptic tissue. From this information, a theory can be put forward on how to compensate for the observed changes. Examples for such targets are among others (*R,S*)-2-amino-3-(3-hydroxy-3-methylisoxazol-4-yl)propionic acid (AMPA) antagonists [17] or potassium channel openers [18]. These targets can be used in modern automated screening systems. However, although this approach may lead to novel targets, these may only coexist with the real causes or the changes in gene expression may only be a compensation initiated by the seizures. This would render even high affinity ligands useless for the treatment of epilepsy. In summary, no superior strategy can be defined to develop new antiepileptic drugs. An approach which involves elements of several strategies may be best in developing new drugs which are superior to the existing ones both in regard to efficacy and tolerability.

2. Antiepileptic Drugs

Landmarks in Antiepileptic Drug Treatment:

1857	Bromides
1912	Phenobarbital
1938	Phenytoin
1958	Ethosuximide
1967	Carbamazepine
1974	Valproic acid
1989	Vigabatrin

1991	Lamotrigine
1993	Gabapentin
1995	Topiramate
1996	Tiagabine

Phenobarbital was the first effective organic antiepileptic agent and the starting point for structural variation leading to hydantoins (phenytoin), succinimides (ethosuximide), and oxazolidinediones (trimethadione). These active chemical classes exhibit certain structural similarities, they all have an imide group and a carbon atom bearing four nonhydrogen substituents. In spite of chemical similarities, the structural variation leads to different anticonvulsant effects. Like phenobarbital, phenytoin is highly effective in suppressing generalized tonic – clonic as well as simple complex partial seizures, and ethosuximide is effective in suppressing absence seizures. Although structural similarities exist between these classes, phenytoin and ethosuximide exert the activity through different mechanisms. Thus, phenytoin blocks voltage dependent Na^+-channels and ethosuximide blocks Ca^{2+}-T-channels.

Therefore, structure-activity relationships can be discussed only within well-defined chemical classes: hydantoins [19], dibenz[b,e]azepines [20], acetic acids [21], succinimides [22], oxazolidinediones [23], barbiturates [24], benzodiazepines [25] or for compounds of different chemical classes which exert anticonvulsant activity essentially through the same mechanism [26].

Current therapeutic use is the criterion for listing a compound in this article. Since the 1980s several new antiepileptic drugs have entered the market. At present the new drugs are an alternative to the old drugs for 25 % of patients with refractory epileptic seizures. The search for effective and cheap drugs which are well tolerated and devoid of side effects still persists. Books on the old and new antiepileptic drugs [27], [28] and reviews of the new antiepileptic drugs [29], [30] have appeared, additional mechanistic aspects are discussed in [31]. The market value of antiepileptics has grown significantly. Worth $\$560 \times 10^6$ in 1987, the market topped $\$2000 \times 10^6$ in 1996 and, if current growth rates continue, could exceed $\$4000 \times 10^6$ by 2000 (currently, 50 % of the antiepileptic drugs are sold in North America). Much of this spectacular growth is due to the premium-priced products entering the market, but the well-established and cheaper drugs (phenytoin, carbamazepine, and valproate) are the mainstay of treatment and still dominate the market [32].

2.1. Phenytoin

Phenytoin [*57-41-0*], 5,5-diphenyl-2,4-imidazolidinedione, $C_{15}H_{12}N_2O_2$, M_r 252.26, *mp* 295 – 298 °C; practically insoluble in water. 1 g dissolves in about 75 ml of ethanol or 30 ml of acetone.

Synthesis:

1) Condensation of benzil with urea [33]

2) Bucherer reaction [34]

Trade names: Difhydan (Leopharm), Dihycon (CMC), Di-Hydan (Carrion), Dilantin (Parke – Davis), Ekko (Fleming), Hydantin (Lääkefarmos), Hydantol (Fujinaga – Sankyo), Lehydan (Abigo), Phenhydan (Desitin Arzneimittel), Phenytoin AWD (Arzneimittelwerk Dresden), Zentropil (Nordmark)

Phenytoin sodium [*630-93-3*], sodium 5,5-diphenylhydantoin, $C_{15}H_{11}NaN_2O_2$, M_r 274.26; 1 g dissolves in ca. 66 ml of water. The aqueous solution is turbid unless the pH is adjusted above 11.7, which is the pH of the saturated solution. 1 g dissolves in 10.5 mL of alcohol. Practically insoluble in ether and chloroform.

Trade names: Antisacer (Wander), Danten (McKesson), Diphantoin (Katwijk), Diphenin (Lannett), Epanutin (Parke – Davis), Minetoin (Helvepharm), Phenhydan (Desitin), Solantyl (Roussel – UCLAF), Zentropil (Nordmark).

Phenytoin and its sodium salt are effective in primarily and secondarily generalized tonic – clonic seizures and are also indicated in simple and complex partial seizures, but not in absence seizures. The intravenous form can be used in status epilepticus. The clinical use of phenytoin is complicated by its narrow therapeutic margin and its saturation kinetics. Side effects include nystagmus, ataxia, slowly progressing impairment of mental function, skin rash, gingival hyperplasia, and hirsutism. The main mechanism of action of phenytoin is based on the blockade of voltage-dependent Na^+-channels.

Phenytoin and its sodium salt are widely used in the USA (18.1 % of the sales in 1995, Western Europe 4.2 %)

Other Hydantoins.

Mephenytoin [*50-12-4*], 5-ethyl-3-methyl-5-phenyl-2,4-imidazolidinedione, can be substituted for phenytoin where the peripheral neuropathy and hirsutism create problems. Side effects, including rash, fever, and fatal blood dyscrasia, prevent the use as an anticonvulsant drug of first choice.

Trade name: Insulton (Sandoz).

Ethotoin [*86-35-1*], 3-ethyl-5-phenyl-2,4-imidazolidindione, has never achieved the status of a drug of choice.

Trade name: Peganone (Abbott).

2.2. Carbamazepine and Oxcarbazepine

Carbamazepine [*298-46-4*], 5*H*-dibenz[*b,f*]azepine-5-carboxamide, $C_{15}H_{12}N_2O$, M_r 236.26, *mp* 189 – 193 °C; soluble in chloroform, DMF, ethylene glycol monomethyl ether, or methanol, only slightly soluble in ethanol or glacial acetic acid, virtually insoluble in water.

Synthesis: 5*H*-dibenz[*b,f*]azepine is first reacted with phosgene and then with ammonia [35].

Carbamazepine is the only antiepileptic combining structural characteristics of classical antiepileptics with those of polycyclic psychoactive agents, such as imipramine (→ Psychopharmacological Agents, Chap. 4.1.1.).

Carbamazepine is the drug of choice for complex partial seizures and is also effective against simple partial and generalized tonic – clonic seizures, but not against absence seizures. Carbamazepine also has an antineuralgic and a psychotropic effect, i.e., a positive influence on disturbed mood and behavior, and little or no detrimental effect on intellectual functions. Side effects include skin rash, headache, nausea, fatigue, vertigo, and ataxia.

The substance is considered to exert its main effect by inhibiting voltage-dependent Na^+-channels.

Carbamazepine is widely used worldwide (15.5 % of the sales in the USA in 1995, 34.7 % in Western Europe).

Trade names: Biston (Spofa), Calepsin (Orion), Carbagamma (Wörwag), Carbamazepin – GRY (GRY – Pharma), Carbamazepin Heumann (Heumann), Carbamazepin – neuraxpharm (neuraxpharm), Carbamazepin – ratiopharm (ratiopharm), Carbamazepin 200 Stada (Stadapharm), Carbelan (Elan), Epitol (Lemmon), Finlepsin (Arzneimittelwerk Dresden), Fokalepsin (Promonta Lundbeck), Sirtal (Sanofi Wintrop), Tegretol (Novartis), Timonil (Desitin Arzneimittel).

Oxcarbazepine [*28721-07-5*], 10,11-dihydro-10-oxo-5*H*-dibenz[*b,f*]azepin-5-carboxamide, $C_{15}H_{12}N_2O_2$, M_r 252.27, *mp* 215 – 216 °C; virtually insoluble in water.

Synthesis: Oxcarbazepine can be obtained in two different ways.

1) Reaction of 10-methoxy-5*H*-dibenz[b,f]azepine (**1**) with phosgene gives the 5-chlorocarbonyl compound, treatment with NH_3 affords 10-methoxy-5*H*-dibenz[*b,f*]azepine-5-carboxamide (**2**), which is hydrolyzed with diluted HCl to oxcarbazepine [36].

2) Nitration of 5-cyano-5*H*-dibenz[*b,f*]azepine (**3**) with $NaNO_3$ in acetic anhydride/acetic acid gives 5-cyano-10-nitro-5*H*-dibenz[*b,f*]azepine (**4**), which is treated with BF_3 and powdered iron in acetic acid [37].

Oxcarbazepine is a new antiepileptic drug (launched in 1990). Compared with its parent drug, carbamazepine, it is metabolized via a different pathway and may have milder side effects. The efficacy of the two drugs seems to be similar.

Trade name: Trileptal (Novartis).

2.3. Valproic Acid

Valproic acid [*99-66-1*], 2-propylpentanoic acid, $C_8H_{16}O_2$, M_r 144.21; colorless liquid, *bp* 221 – 222 °C at 101.3 kPa, $n_D^{25} = 1.425$, $d_4^{25} = 0.904$; soluble in most organic solvents, including methanol, chloroform, and ether, solubility in water: 1.27 mg/mL.

Trade names: Convulex (Promonta Lundbeck), Mylproin/Orfiril (Desitin Arzneimittel), Mylproin (ICI).

Sodium valproate [*1069-66-1*], $C_8H_{15}NaO_2$, M_r 166.20, colorless crystalline powder, hygroscopic, very soluble in water (ca. 0.66 g/mL of solution), soluble in ethanol (ca. 0.2 g/mL of solution), practically insoluble in chloroform and diethyl ether.

Trade names: Convulex (Byk – Gulden, Promonta Lundbeck), Depakene/Depakote/Valcote (Abbott), Depakine/Epilim/Ergenyl (Sanofi), Leptilan (Novartis), Orfiril (Desitin Arzneimittel).

Calcium valproate [*138995-18-3*], $C_{16}H_{30}CaO_4 \cdot 2H_2O$, M_r 362.5

Trade name: Convulsofin (Arzneimittelwerk Dresden).

Magnesium valproate [*62959-43-7*], $C_{16}H_{30}MgO_4$, M_r 310.73.

Trade name: Logical (Armstrong).

Synthesis: Diethyl malonate is alkylated with 1-bromopropane and then hydrolyzed and decarboxylated [38].

Valproic acid and its salts are major antiepileptic drugs for the treatment of absence, myoclonic, and generalized tonic – clonic seizures and also may be effective against complex partial seizures. The most common side effects are gastrointestinal disturbances and sedation. The most serious adverse effect is liver damage, although this is rare. Teratogenic effects, predominantly spina bifida, are reported frequently. The mechanism of action of valproic acid is not certain. The most cited mecha-

nisms are the increase in GABA function and the blockade of voltage-dependent Na^+-channels.

Valproic acid and its salts are the most widely used antiepileptic drugs worldwide (25.6 % of the sales in the USA in 1995, 31.5 % in Western Europe).

2.4. Ethosuximide and Trimethadione

Ethosuximide [*77-67-8*], 3-ethyl-3-methyl-2,5-pyrrolidinedione, $C_7H_{11}NO_2$, M_r 141.17, *mp* 64 – 65 °C; very soluble in water.

Synthesis: The condensation of butanone with cyano ethyl acetate and subsequent reaction with NaCN and H_2SO_4 gives 2-ethyl-2-methylsuccinic acid (**5**), which is ring-closed via the diammonium salt to yield ethosuximide [39].

Ethosuximide is the most effective succinimide against absence seizures. It acts by blockade of T-type Ca^{2+}-channels in thalamic neurons.

Ethosuximide is a useful and unique antiepileptic drug, but for the most forms of absences valproic acid is the drug of first choice.

Trade names: Epileo Petitmal (Eisai), Pemal (Benzon), Petnidan (Desitin Arzneimittel), Suxilep (Parke – Davis, Jenapharm), Suxinutin/Zarontin (Parke – Davis).

Phensuximide [*86-34-0*], 1-methyl-3-phenyl-2,5-pyrrolidinedione

Trade name: Mirontin (Parke – Davis).

Methsuximide [*77-41-8*], 1,3-dimethyl-3-phenyl-2,5-pyrrolidinedione

Trade name: Cerontin (Parke – Davis).

Phensuximide and methsuximide have also some efficacy against complex partial seizures.

Trimethadione [*127-48-0*], 3,5,5-trimethyl-1,3-oxazolidine-2,4-dione, $C_6H_9NO_3$, M_r 143.14, *mp* 46 – 46.5 °C; slight camphorlike odor, burning faintly bitter taste; solubility in water about 5 %, freely soluble in chloroform, ethanol, and diethyl ether.

Synthesis: Ethyl 2-hydroxy-2-methylpropionate (**6**), obtained by reaction of acetone and KCN, is condensed with urea in the presence of sodium ethoxide to give 5,5-dimethyl-1,3-oxazolidine-2,4-dione (**7**), which is methylated with dimethyl sulfate to form trimethadione [40].

Trimethadione is effective against absence seizures, but its clinical use is very limited because of its toxicity.

Trade names: Absentol (Nourypharma), Epidione (Bellon), Ptimal (EGIS), Tridione/Trimedone (Abbott).

The share of succinimide and oxazolidine drugs in the world market is < 5 %.

2.5. Phenobarbital and Primidone

Phenobarbital [*50-06-6*], phenobarbitone, 5-ethyl-5-phenyl-2,4,6(1*H*,3*H*,5*H*)-pyrimidinetrione, $C_{12}H_{12}N_2O_3$, M_r 232.23; (synthesis and properties of phenobarbital and other barbiturates → Hypnotics, Chap. 5.1.).

Phenobarbital is highly effective in suppressing generalized tonic – clonic as well as simple and complex partial seizures; however, its clinical use is limited because of its serious side effects: fatigue, drowsiness, irritability, and especially deterioration of higher cerebral functions (attention memory, and intellectual performance). Intravenous use in status epilepticus may lead to severe respiratory depression. Phenobarbital potentiates inhibitory GABAergic and inhibits excitatory glutamatergic neurotransmission through interaction with modulatory binding sites on the respective neurotransmitter receptors.

Trade names: Agrypnal (Eggochemia), Eskabarb (SKF), Lepinal (Arzneimittelwerk Dresden), Luminal (Winthrop, E. Merck, Desitin Arzneimittel), Phenobal (Fujinaga).

Methylphenobarbital [*115-38-8*], 5-ethyl-1-methyl-5-phenyl-2,4,6(1*H*,3*H*,5*H*)-pyrimidinetrione, is regarded as a prodrug for phenobarbital and has an advantage over phenobarbital because it produces plasma phenobarbital levels that vary in direct proportion to drug dose.

Trade name: Mebaral (Winthrop).

Primidone [*125-33-7*], 5-ethyldihydro-5-phenyl-4,6(1*H*,5*H*)-pyrimidinedione, $C_{12}H_{14}N_2O_2$, M_r 218.25, *mp* 281 – 282 °C; slightly bitter taste; sparingly soluble in water (0.6 g/L at 37 °C) and most organic solvents.

Synthesis: Primidone is obtained by reductive desulfurization of 2-thiophenobarbital with Raney nickel or zinc and formic acid, or by ring closure of ethylphenylmalonamide with formamide or formic acid [41].

Primidone is effective against most generalized and partial seizure types, but its clinical use is limited because of its serious side effects, which are similar to those of its main metabolite, phenobarbital. Although primidone is a prodrug for phenobarbital its antiepileptic properties are independent of phenobarbital.

Trade names: Liskantin (Desitin Arzneimittel), Mylepsin (ICI), Mylepsinum (Zeneca), Resimatil (Sanofi Winthrop), Mysoline (Wyeth – Ayerst), Sertan (Chinoin).

Phenobarbital and primidone are rarely used worldwide (share < 5 % of the sales of antiepileptics in 1995).

2.6. Benzodiazepines (→ Hypnotics, Chap. 5.4., → Sedatives, Chap. 3.1., → Psychopharmacological Agents, Chap. 4.1.)

Clonazepam [*1622-61-3*], 5-(2-chlorophenyl)-1,3-dihydro-7-nitro-2*H*-1,4-benzodiazepin-2-one, $C_{15}H_{10}ClN_3O_3$, M_r 315.72; *synthesis:* [42].

Trade names: Antelepsin (Arzneimittelwerk Dresden), Clonopin/ Rivotril (Roche).

The other 1,4-benzodiazepines, diazepam [*439-14-5*], 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one, *trade name*: Valium (Roche), (→ Psychopharmacological Agents, Chap. 4.1.1.) and nitrazepam [*146-22-5*], 1,3-dihydro-7-nitro-5-phenyl-2*H*-1,4-benzodiazepin-2-one, *trade name*: Mogadon (Roche), (→ Hypnotics, Chap. 5.4.) as well as the 1,5-benzodiazepine clobazam [*22316-47-8*], 7-chloro-1-methyl-5-phenyl-1*H*-1,5-benzodiazepine-2,4(3*H*,5*H*)-dione, *trade name*: Frisium, (Hoechst), (→ Psychopharmacological Agents, Chap. 4.1.2.) have been in clinical use for a long time.

The major clinical use of the benzodiazepines in epilepsy is in the initial treatment of status epilepticus. They are also effective in a variety of

other seizure types, but tolerance to their effects usually develops early in the course of treatment. For this reason they are used mostly for adjunct therapy in refractory cases.

The antiepileptic activity of benzodiazepines is mediated primarily by an enhancement of GABAergic synaptic transmission.

The benzodiazepines are widely used (sales of clonazepam in USA in 1995 26.3 %, in Western Europe 2.2 %).

2.7. New Drugs

Since the 1980s several new drugs have been approved or are in the process of being approved, e.g., vigabatrin, felbamate, zonisamid, lamotrigine, gabapentin, topiramate, and tiagabine (oxcarbazepine see Section 2.2). At present, the main use of the new agents is in patients that are refractory to first-line drugs such as carbamazepine or valproate. Further studies are required to characterize their activity spectrum as well as their potential value in monotherapy [29], [30].

Vigabatrin [*60643-86-9*], 4-amino-5-hexenoic acid, $C_6H_{11}NO_2$, M_r 129.16, *mp* 171 – 177 °C; off-white crystals; solubility: water 335 mg/mL, ethanol 7.5 mg/mL, chloroform 0.1 mg/mL.

Synthesis: The reaction of 1,4-dichloro-2-butene with diethyl malonate in the presence of sodium ethoxide as catalyst in refluxing ethanol gives 1,1-bis(ethoxycarbonyl)-2-vinylcyclopropane (**8**), which by reaction with gaseous ammonia in DMF is converted into 3-carboxamido-5-vinyl-2-pyrrolidone (**9**). This compound is treated with HCl in refluxing acetic acid to yield vigabatrin [43].

Vigabatrin has a good efficacy profile in partial seizures. However, anticonvulsant efficacy is lost in up to 50 % of patients due to development of tolerance. Side effects are weight gain and effects on mood and behavior. It has been found that vigabatrin potentates the GABAergic transmission through inhibition of GABA-transaminase.

Trade name: Sabril (Merrell Dow).

Lamotrigine [*84057-84-1*], 3,5-diamino-6-(2,3-dichlorophenyl)-1,2,4-triazine, $C_9H_7Cl_2N_2$, M_r 256.09, *mp* 216 – 218 °C; off-white crystals; pk_a 5.5.

Synthesis: The reaction of 2,3-dichlorobenzoyl chloride (**10**) with $Cu(CN)_2$ and KI in refluxing xylene yields 2,3-dichlorobenzoylcyanide (**11**), which is cyclized with aminoguanidine in DMSO [44].

Lamotrigine is considered to be effective in different seizure types and it is well tolerated. The main mechanism of action is the blockade of voltage dependent Na^+-channels. Severe skin rashes can necessitate the stop of the treatment.

Trade name: Lamictal (Wellcome).

Gabapentin [*60142-96-3*], 1-(aminomethyl)cyclohexaneacetic acid, $C_9H_{17}NO_2$, M_r 171.24, *mp* 165 – 167 °C; off-white crystals; zwitterion at physiologic pH; highly water soluble.

Synthesis: The synthesis is started with the Guareschi salt (**12**) (obtained from cy-

clohexanone and cyanoacetate), which is hydrolyzed and decarboxylated to give 1,1-cyclohexanediacetic acid. The anhydride can be treated either with methanol to yield the half ester (**13**) or with hydroxylamine to afford the *N*-hydroximide (**14**). The half ester is converted to the azide and subjected to a Curtius-type rearrangement to give the isocyanate (**15**) which is hydrolyzed to gabapentin. Gabapentin is also obtained from the corresponding *N*-hydroxyimide (**14**) via a Lossen-type rearrangement by conversion of (**14**) to *N*-benzenesulfonyloximide and following reaction with triethylamine to the urethane ester (**16**) [45].

Gabapentin has a good tolerability. Dizziness, fatigue, somnolence, ataxia and tremor are relatively common. Its short half-life in the body is a disadvantage. Gabapentin binds with high affinity to a branched amino acid transporter. This may be the reason for increased GABA-levels in certain region of the brain during therapy with gabapentin.

Trade name: Neurontin (Warner – Lambert).

Topiramate [*97240-79-4*], 2,3:4,5-bis-*O*-(1-methylethylidene)-β-D-fructopyranose sulfamate, $C_{12}H_{21}NO_8S$, M_r 339.36, *mp* 125 – 126 °C; $[\alpha]_D^{24} = -34.0$; soluble in methanol.

Synthesis: D-Fructose is reacted with acetone to produce the bisacetonide (**17**). This compound is then condensed with sulfamoyl chloride in presence of sodium hydride [46].

Topiramate has a good efficacy profile in partial seizures and probably a broad spectrum. Its mechanism of action includes blockade of voltage-dependent Na^+-channels, potentiation of GABA response, antagonism of Kainate/AMPA receptor sites, and inhibition of carbonic anhydrase. Clinically significant adverse effects associated with topiramate are fatigue, dizziness, somnolence, impaired concentration, ataxia, and weight loss.

Trade name: Topamax (Johnson & Johnson).

Tiagabine [*115103-54-3*], (*R*)-(−)-1-[4,4-bis(3-methyl-2-thienyl)-3-butenyl]-3-piperidinecarboxylic acid hydrochloride, $C_{20}H_{25}NO_2SO_2 \cdot HCl$, M_r 412.0, *mp* 193 – 195 °C; off-white, nonhygroscopic, crystalline powder; sparingly soluble in water.

Synthesis: Bromobis(methylthienyl)butene (**18**) is reacted with *R*-(−)-ethyl-3-piperidine carboxylate (**19**) and subsequently hydrolyzed to give the free base which is converted to the hydrochloride [47].

Tiagabine is considered to show a similar activity as vigabatrin or lamotrigine against refractory partial seizures in randomized-controlled add-on trials. Tiagabine exerts its effect by enhancement of GABAergic transmission through inhibition of GABA reuptake. Dizziness, headache, tremor, impaired concentration, and fatigue are common side effects.

Trade name: Gabitril (Abbott).

Felbamate [*25451-15-4*], 2-phenyl-1,3-propanediol dicarbamate, $C_{11}H_{14}N_2O_4$, M_r 238.24, *mp* 150.3 – 151.2 °C; white crystalline powder; solubility in water 0.33 mg/mL, in ethanol 5.0 mg/mL, and in DMF 333.4 mg/mL.

Synthesis: The synthesis of felbamate was first published in 1959. 2-Phenyl-1,3-propanediole is reacted with ethylcarbamate to yield felbamate [48].

Felbamate is effective in Lennox – Gastaut syndrome and it is considered to act by blockade of voltage-dependent Na^+-channels, antagonism of excitatory transmission, through an action on the glycine modulatory site of the NMDA receptor, and potentiation of GABA response. Felbamate, however, has been associated with a high risk of aplastic anemia and hepatotoxicity.

Trade names: Felbatol (Carter – Wallace), Taloxa (Schering – Plough).

Zonisamide [*68291-97-4*], 1,2-benzisoxazole-3-methane-sulfonamide, $C_8H_8N_2O_3S$, M_r 212,23, *mp* 164 – 168 °C; white to pale yellow crystals or crystalline powder; freely soluble in acetone, sparingly soluble in ethanol (95 %), soluble in water 0.8 mg/kg at pH 7.

Synthesis: The reaction of 3-bromomethyl-1,2-benzisoxazole with sodium sulfite in methanol/water gives sodium 1,2-benzisoxazole-3-methanesulfonate, which is converted into 1,2-benzisoxazole-3-methanesulfonyl chloride. Treatment with NH_3 gives zonisamide [49].

Clinical trials have shown zonisamide to be a promising drug for treating a wide variety of seizures. Studies on zonisamide's cellular mechanism of action have demonstrated that the drug blocks voltage-sensitive Na^+- and Ca^{2+}-channels. Relatively common side effects are anorexia, ataxia, dizziness, fatigue, somnolence, impaired concentration, and confusion.

Trade names: Aleviatin (Warner – Lambert), Exceglan/Excegram (Dainippon).

2.8. Other Antiepileptic Drugs

Sulfonamides. The sulfonamides acetazolamide and sulthiam have been known as anticonvulsants since 1952 and 1960, respectively. In most patients, the development of tolerance limits their usefulness as antiepileptic drugs. Their anticonvulsant action is due to the inhibition of carbonic anhydrase.

Acetazolamide [*59-66-5*], *N*-[5-(aminosulfonyl)-1,3,4-thiadiazol-2-yl]acetamide, 2-acetylamino-1,3,4-thiadiazole-5-sulfonamide, $C_4H_6N_4O_3S_2$, M_r 222.25, (→ Diuretics, Chap. 2.).

Trade name: Diamox (Lederle).

Sulthiam [*61-56-3*], 4-(tetrahydro-2*H*-1,2-thiazin-2-yl)benzenesulfonamide *S,S*-dioxide, $C_{10}H_{14}N_2O_4S_2$, M_r 290.37; (synthesis [50]).

Trade name: Ospolot (Desitin Arzneimittel).

Bromides were first introduced as antiepileptic drugs into therapy in 1857. Side effects and ongoing difficulties in defining a therapeutic range of bromide therapy made their use become obsolete. Now these drugs encounter a kind of comeback because of their good activity against tonic – clonic seizures in refractory patients.

Potassium bromide, KBr, *trade name*: Dibro-Be mono (Dibropharm).

1. Introduction

Antifreeze is a material that is added to water or water-containing liquids to lower their freezing points. The liquid whose freezing point is lowered is usually water. The largest single use of antifreeze is to protect internal combustion engines from the damage that can result to the engine and to the radiator when water freezes. Antifreeze finds additional smaller volume uses in refrigeration, heat transfer, and water heating systems, building air conditioners, solar energy units, automatic sprinklers, hydraulic systems, snow-melting equipment, ice skating rinks, deicing fluids, water-based paints, pharmaceutical products, and freeze-drying apparatus. Antifreeze has been produced in the United States since 1920, and in European countries for over 50 years.

The antifreezes produced for automobiles, trucks, and other vehicles mostly use formulations based on ethanediol, 1,2-ethanediol, ethylene glycol [*107-21-1*]. Applications of ethanediol as antifreeze in internal combustion engines are the major emphasis of this article (→ Ethylene Glycol).

2. Antifreeze Materials [1], [2]

Early in the development of internal combustion engines, *water* was selected as the coolant. The reasons for this selection were its availability, low cost, and good heat-transfer properties compared to other materials. However, water has a number of disadvantages:

1) Under normal operating conditions it may be corrosive to metals found in cooling systems.
2) It has a relatively high freezing point.
3) On freezing water expands its volume by 9 – 10 %. This change in volume is sufficient to rupture engine blocks, water pumps, and radiators.

These disadvantages may be overcome by adding antifreeze and corrosion inhibitors. Because water has a relatively low boiling point (100 °C), pressure caps are used to increase the boiling point of the coolant. However, the maximum pressure is limited by the materials of construction, particularly of the radiator, and by the solder used to seal joints in the radiator. The use of ethanediol as an antifreeze elevates the coolant's boiling point, circumventing the problem of using high pressures to achieve higher coolant temperatures.

During the 1920s, United States motor vehicle registration increased from 7.5×10^6 to 26.5×10^6 with a corresponding increase in the need for antifreeze. During this period, denatured *ethanol* (ethyl alcohol) became an important antifreeze because of its availability, low cost, and relatively good freezing point depressing efficiency in aqueous solutions. Although glycerol (1,2,3-trihydroxypropane) was used as

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a03_023

a substitute antifreeze, the amount available for this use varied considerably depending on the overall market for it. Calcium chloride and other salt solutions also were used as engine coolants in parts of the United States. However, because of the corrosiveness of the brine solutions, these did not become well-established antifreeze materials. In addition honey and sugar solutions and, occasionally, kerosene and other hydrocarbon oils were used as engine coolants. None of these materials gained widespread use. *Ethanediol* also made its appearance during the 1920s and proved to be an excellent antifreeze; however, initially, its availability limited its use.

Prior to World War II (1940), the principal antifreeze materials available were ethanol, synthetic *methanol,* and ethanediol, accounting for 90 % of the United States antifreeze consumption. The remaining requirements were served by wood byproduct methanol, glycerol, and 2-propanol (isopropyl alcohol). During World War II, ethanol, methanol, and ethanediol remained the dominant antifreeze materials; however, availability rather than cost or performance was the primary criterion for using a particular material.

Following World War II (1945), the increase in the number of vehicles in both the United States and Western Europe heightened the demand for antifreeze materials. During this period, coolants based on methanol and ethanediol were used almost exclusively. Methanol-based coolants reached maximum consumption in the early 1950s. By then car manufacturers had begun to install ethanediol in new car production, and by the early 1970s they were using only this material. Similarly, the entire market for replacement automotive engine coolants shifted to ethanediol. By 1960 ethanediol had increased its market share to > 80 % [3]. Methanol-based coolants, used in some stationary engines and required in older engines, hold a small and decreasing share of the coolant market.

The main factor that has displaced methanol coolants in favor of ethanediol in automotive use is the higher coolant operating temperatures required to achieve superior space heating in vehicle interiors during cold weather. Higher coolant operating temperatures also result in slight improvements in vehicle fuel efficiency.

Antifreezes based on *1,2-propanediol,* propylene glycol (→ Propanediols), are used as heat transfer fluids in systems where toxicity of the antifreeze poses a problem, e.g., in some active solar energy collectors, in cooling systems of engines operating potable water sources, and in freezing and refrigeration systems for food and dairy products. The use of 1,2-propanediol as an automotive antifreeze in some European countries (e.g., Switzerland) is more widespread than in the United States because of its reduced potential for poisoning humans, particularly children, by accidental ingestion.

1-Methoxy-2-propanol also has been used as an antifreeze material, principally in ebullient cooling systems and in some heavy-duty diesel engines. Because an azeotrope is formed between 1-methoxy-2-propanol and water, freeze protection also is provided in the vapor phase in ebullient cooling applications.

1-Methoxy-2-propanol-based antifreeze-shave applications in heavy-duty diesel engines and other industrial engines where coolant seep age into the crankcase is a problem [4]. Because of low volatility ethanediol remains in the crankcase, resulting in sludge and varnish formation and thereby causing accelerated bearing wear. On the other hand, 1-methoxy-2-propanol is more volatile and is more readily expelled along with water vapor through the crankcase vent system.

1-Methoxy-2-propanol also maintains lower metal temperatures than comparative glycol-based coolants [5]. This was an advantage in rotary engines. However, with the nearly complete disappearance of these engines, this advantage is no longer a major market factor.

3. Physical Properties

The physical properties of water and several common antifreeze materials are given in Table 1.

Antifreeze–water mixtures exhibit unusual freezing behavior compared to each pure material or to dilute aqueous solutions. When freezing begins, these mixtures do not form a solid – liquid equilibrium with the same chemical composition in both phases. The higher freezing component, water, starts to crystallize first. This increases the concentration of antifreeze in the liquid, lowering its freezing point. The mixture behaves as a slush over a much

Table 1. Physical properties of water and several antifreeze compounds [6]

wider temperature range than either pure material.

Whereas the freezing point depression of antifreeze–water mixtures can be easily computed for dilute solutions, this is not the case for the corrosion-inhibited antifreezes that are in general use. Approximate freezing points can be estimated from data generated from mixtures of water and uninhibited antifreeze compounds (Fig. 1). Exact freezing points are best determined by actual measurement (a convenient method is given in ASTM Standard Test Method D 1177 [7]).

Figure 1. Freezing points of various antifreeze–water solutions [6]

Along with the freezing point, antifreeze materials affect the boiling point of water. Permanent antifreezes raise the boiling point of the mixture above 100 °C. Table 2 gives the boiling points of several uninhibited antifreeze–water mixtures [8]. Methanol, unlike the other anti freezes in the table, actually decreases the boiling point of the solution below that of water. Because corrosion inhibitors also increase the boiling point of water, exact boiling points must be determined on the actual mixture (ASTM Standard Test Method D 1120 [7]).

Other physical properties of antifreeze–water mixtures that impact equipment design, such as viscosity, thermal conductivity, specific heat, and specific gravity, can be obtained from product bulletins or engineering handbooks [9].

4. Corrosion Inhibitors

Corrosion protection of the engine and associated cooling/heating system is another important function of the formulated antifreeze. Because antifreeze – water solutions can be more corrosive than water alone, corrosion inhibitors are added to give efficient corrosion protection and also to hinder the oxidation of ethanediol to corrosive derivatives.

Solution corrosivity is a complex function of antifreeze base, type and combinations of metals used, nature of heat rejection surfaces, and cooling system temperatures. The quality of the water is also important. Anions of strong acids, such as chloride or sulfate, can increase the solution corrosivity.

In the United States coolant inhibitor formulations are made without regard to water quality. This permits the use of a wide variety of inorganic materials that might otherwise not be used, such as orthophosphate.

Formulations with low corrosiveness are produced by combining ethanediol with inhibitors from the following groups: phosphates, benzoates, sebacates, borates, nitrates, nitrites, silicates, or molybdates, or organic compounds, such as amines, benzothiazoles, benzotriazoles,

Table 2. Boiling points, °C, of mixtures of water and various uninhibited antifreezes (at 101.3 kPa) [8]

Antifreeze, %	Methanol	Ethanediol	1,2-Propanediol	1-Methoxy-2-propanol
10	91.7	101	101	100

60	74	110	107	103

or imidazoles (e.g., triethanolamine phosphate, sodium benzoate, sodium nitrate).

The amount of each is based on the formulator's experience as to what is necessary for the desired corrosion protection. General Motors' specification GM 6038-M (see Table 3) contains the typical inhibitors found in most antifreezes produced in the United States.

Table 3. Antifreeze composition specifications, General Motors

	GM 6038-M (parts by wt)	GM 6043-M (wt %)
Ethylene glycol [a]	1115.5	95.5

Sodium 2-mercapto-benzothiazole (50 wt % solution)	6.5	0.5
Sodium tolyltriazole (50 wt % solution)	–	0.2
Antifoam [c]	0.5	0.05
Dye [d]	0.05	0.005
Water	– [e]	2.3
Silicate antigel [f]	–	0.06

[a] 90 wt % minimum monoethylene glycol, 10 wt % maximum other glycols;
[b] Liquid sodium silicate contains a $SiO_2 : Na_2O$ ratio of 3.22 : 1, by weight;
[c] Pluronic L-61 or equivalent;
[d] Uranine C and Alizarine Cyanine Green G-extra or equivalents in a weight ratio of 2 and 3 parts, respectively;
[e] Water may be added to aid the dissolution of salts consistant with the composition maintaining a −37 °C, maximum, freezing point when mixed 50 vol % with distilled water;
[f] Union Carbide silicate stabilizer Y-9794 or equivalent.

In both Europe and the United States, some automotive manufacturers limit the use of materials, such as the combination of amines or nitrites, that may react to form carcinogenic compounds.

In Europe the coolant must be compatible with local hard water. Such materials as orthophosphate and, in some areas silicate, cannot meet this criterion. Benzoate is an alternative to orthophosphate. Amine salts are used only in some special applications where the specifications have not been changed to get improved formulations.

Inhibited antifreezes used in Japan are similar to those used in the United States, except triethanolamine [*tris*(2-hydroxyethyl)amine][*102-71-6*] is frequently used as the neutralizing base.

5. Production

Most antifreezes are formulated products. The major ingredient is the freezing point-depressing fluid. In automotive antifreeze concentrates, ethanediol represents greater than 94 wt % of the formulated product. The remaining ingredients are metal and glycol antioxidants, water, and minor amounts of other additives, e.g. to prevent foaming and to provide a distinctive color.

Antifreeze formulations are manufactured in a batch operation using a tank equipped with an agitator. The tank may also contain heating coils to facilitate the dissolution of additives. In the case of ethanediol-based antifreeze, the blending tank is usually constructed of mild steel or glass-fiber-reinforced resin. Rubber-lined tanks are incompatible with ethanediol.

Manufacturers of the antifreeze base may or may not have their own blending facilities. Many regional facilities offer blending and packaging services on a contract basis. This provides more economical distribution of antifreeze products.

6. Environmental Protection

Antifreeze materials are most likely to enter the aquatic environment after use. Both ethanediol and 1,2-propanediol have low toxicity to animals, plants, and a variety of microorganisms.

However, discharge of excessively high concentrations of glycols in localized areas of the environment should be avoided. Dilute aqueous solutions are rapidly degraded biologically to carbon dioxide and water, whereas concentrated solutions can overload the biologic capacity of the environment to degrade these materials. In summary dilute solutions of glycols present little threat to the environment, and therefore, glycol-based antifreezes represent minor disposal problems.

7. Quality Specifications

Ethanediol-based antifreeze is manufactured to meet either performance or composition specifications. *Performance specifications* define the attributes antifreeze must have, without restricting the composition of the product. Performance specifications normally include:

1) The acceptable maximum freezing points and minimum boiling points of the aqueous solutions
2) The minimum acceptable levels of corrosion performance in vehicle and/or laboratory tests
3) The acceptable effect on elastomers used in vehicle cooling systems
4) The acceptable effect on vehicle finishes

Some performance specifications do place limited restrictions on antifreeze composition, for example, by excluding or limiting the use of some additives, or specifying ranges of physicochemical properties.

Composition specifications prescribe the precise identity and amount of each chemical used to manufacture the antifreeze.

Antifreeze specifications and performance requirements are determined by three major purchasing groups: vehicle manufacturers, consumers, and government agencies. Vehicle manufacturers generally purchase antifreeze to meet their own performance specifications. General Motors has two composition specifications, GM 6038-M and GM 6043-M [10] (see Table 3). The latter specification was issued in 1983 to provide greater corrosion protection of aluminum cooling system parts. The performance specification designations (ca. 1983) of the major automobile manufacturers are:

AMC	AM 4085
BMW	BMW N 60069.0
Chrysler (USA)	MS 7170
Daimler Benz	DBL 7700
Fiat	5552311
Ford (USA)	ESE M 97 B 44-A
Ford (Europe)	SSM-97 B 9101-A
General Motors (USA)	GM 1825-M
General Motors (Europe)	GME L6 368
Honda	Z 009 – 75
Nissan	NES M 5059
Renault	41 – 01 – 001
Toyo Kogyo	TES K 221 – 78
Volkswagen	TL-VW 774
Volvo	STD 1285.05

In the United States, the American Society for Testing and Materials (ASTM) plays a prominent role in determining the quality specifications of antifreeze marketed to consumers. The ASTM Committee D 15 on Engine Coolants has established a Standard Specification for Ethylene Glycol Base Engine Coolant (Standard D-3306). Many states requiring registration of antifreeze products have incorporated this specification into legislation (see Chap. 10) governing the distribution and sale of antifreeze.

Both military and civilian agencies are involved in government purchases of antifreeze products. In the United States, national civilian government agency purchases are made using General Services Administration Federal Specification O-A-548 D, which is a performance specification. Military purchases are made using primarily composition specifications.

8. Chemical Analysis

Analysis of antifreezes provides information about either the bulk properties of the fluid or the individual components of the mixture. Recommended ASTM test methods [7] for the most common *bulk properties* are:

f_P	D 1177
	D 3321
bp	D 1120
Specific gravity	D 1122
pH	D 1287
Reserve alkalinity	D 1121
Foaming dependency	D 1881
Ash content	D 1119
Effect on automotive finishes	D 1882

Freezing point is probably the most important of the bulk properties. When exact freezing points are needed Test Method D 1177 is recommended, but if a freezing point within 1 °C of the ethanediol base fluid is all that is required, Test

Method D 3321 is used because it can be easily followed by persons with minimal training.

Solution pH, reserve alkalinity (buffer capacity), and ash content are gross measures of corrosion inhibitor levels. Quantitation of individual corrosion inhibitor compounds gives a clearer view of the condition of the fluid. Knowledge of the absence or presence of corrosion products is also useful, particularly in maintaining large-volume cooling systems of stationary engines. The analytical methods suggested for measurement of individual components are:

Water content of antifreeze concentrates	Karl Fisher titration [11]
Anion corrosion inhibitors	ion chromatography [12]
Ethylene glycol content of antifreeze concentrates	gas chromatography [13]
Boron, silicon, and metallic corrosion products	direct current plasma spectrometry [14]
Organic, copper, brass, and solder corrosion inhibitors	liquid chromatography [15]

9. Storage and Transportation

Ethanediol-based antifreeze concentrate has a flash point of approximately 120 °C and therefore should be handled as a flammable substance. Aqueous antifreeze solutions do not support combustion. Ethanediol has an ignition temperature of 402 °C, and may have been responsible for a vehicle fire resulting from ignition by a hot exhaust manifold [16].

Bulk quantities of ethanediol-based antifreeze concentrates are generally stored in carbon steel tanks. Storage in resin-coated, stainless steel, or aluminum containers is also satisfactory. The material should not be permitted to come in contact with strong oxidizing agents. Ethanediol is hygroscopic; therefore, long, open exposure to a moist atmosphere should be avoided to assure maintaining product quality specifications.

Smaller quantities of ethanediol-based antifreeze concentrate are stored in sealed carbon steel or high-density polyethylene containers. In these packages product integrity is maintained for an indefinite period.

Antifreeze is distributed in a wide variety of lot sizes ranging from barge lots (ca. 1×10^6 L) to packages as small as 1 quart (0.95 L). Packaging materials for ethanediol-based antifreeze include steel and high-density polyethylene containers. Both packaging materials are relatively impervious to chemical attack by ethanediol-based antifreeze and therefore permit long-term storage in the product distribution chain.

Although regulations exist relating to the packaging of ethanediol-based antifreeze products (see Chap. 10), no specific regulations apply in the United States to the transportation of these products over land or water.

10. Legal Aspects

During the last two decades, a number of United States government regulations have been enacted regarding the packaging, labeling, and registration of antifreezes [17]. Specific state registrations for antifreeze include minimum performance characteristics. Similar to these state registrations are the regulations that exist in Western Europe. These regulations will certainly impede the introduction of new antifreeze materials in the coming years and will probably insure continued use of ethanediol-based antifreezes.

11. Uses

The principal use for antifreeze is the protection of vehicle cooling systems. Other applications are in the cooling systems of stationary engines used in petroleum and natural gas pipelines and in other industrial systems that require freeze and corrosion protection of cooling/heating systems.

The principal reason for using antifreeze is to prevent the possibility of damage to liquid cooled/heating equipment that may intermittently or continuously operate below the freezing point of water. Factors that influence the choice of antifreeze material include:

1) The heat capacity of the fluid
2) The viscosity of the fluid
3) The metallurgy in the system
4) The nonmetallic components in the system
5) The flammability of the fluid
6) The toxicity of the fluid
7) Other special operating considerations

12. Trade Names

In Europe automotive antifreeze sold to consumers (replacement antifreeze) is distributed predominantly through vehicle maintenance centers, together with other maintenance and replacement parts. The products are sold under trade names of the manufacturers or under the specific brand names of trading companies and supermarkets. Some examples are: ARAL-Frostschutz (ARAL), DOW FROST (Dow Chemical), Fricofin (Fuchs Mineralölwerke), Frostschutz 500 (Mobil Oil), Frostschutz UT 184 (BP Chemie), Gefrierschutz-Glykol (Hüls), Genantin (Hoechst), Glycoshell (Shell-Chemie), Glysantin (BASF), and others.

Antifreeze also is offered under trade names of the automobile manufacturer or associated companies, e.g., Antigels (Renault), Frostschutz (Opel), Motorcraft (Ford), Frostschutz G 11 (VW).

In the United States and Canada, consumer antifreezes are marketed predominantly under trade names registered to ethanediol manufacturers. Examples of nationally distributed brands in the United States include: Dowguard (Dow Chemical), Peak (Norchem, Inc.), Prestone II (Union Carbide), Shellzone (Shell Chemical), Startex (Texaco Chemical), and Zerex (DuPont). In addition a large number of companies purchase ethanediol and market trade-named antifreezes on both a regional and a national basis. Vehicle manufacturers also purchase and distribute antifreeze bearing their own trade name.

Several United States glycol manufacturers are involved in marketing ethanediol-based antifreeze specifically for industrial, nonautomotive applications. Included in this group are: Dow Chemical (Ambitrol coolant), Norchem, Inc. (Norkool coolants), Texaco Chemical Co. (Jeffcool coolant), and Union Carbide (Ucartherm coolant). Other glycol-based fluids are sold for highly specialized applications, such as heavy-duty diesel engine coolants, e. g., Dowtherm 209 (Dow Chemical) and Compleat (Fleetguard); and for heat-transfer fluids for food and dairy applications, e.g., Dowfrost (Dow Chemical) and Ucar Food Freeze (Union Carbide).

13. Economic Aspects

Antifreeze represents a major end-use market for ethanediol. In the United States approximately 40 % of all ethanediol production is used to manufacture antifreeze [18].

Producers of ethanediol in the United States are (ca. 1983 capacities, 10^3 t/a) [19].

BASF Wyandotte	159
Celanese	227
Dow Chemical (USA)	322
Eastman Chemical	85
ICI American	181
Norchem, Inc.	91
Olin	18
PPG Industries	91
Shell Chemical	181
Texaco Chemical	227
Union Carbide	1316
Total	2898

Ethanediol production capacities for other countries are (ca. 1983, 10^3 t/a):

Canada	327 [19]	
Mexico	191	
Belgium	260	290 [20]
France	215	165
Federal Republic of Germany	325	315
Italy	106	60
Netherlands	304	334
Spain	68	69
Sweden	20	5
United Kingdom	230	255
Japan	733	
Total	2779	

In 1981, United States plants were estimated [21] to be operating at 68 % of nameplate capacity. New plant capacities have been announced in the Middle East, Canada, and several developing countries for startup in the mid-1980s.

The Chemical Specialties Manufacturer's Association annually tabulates the volume of antifreeze shipments from all United States manufacturers (Fig. 2) [22]. The leveling off of total ethanediol-based antifreeze shipments (solid line) is ascribed to decreasing new car production, longer new car maintenance intervals, and decreasing capacity of automobile cooling systems. The cooling system capacity is expected to continue decreasing as the automobile industry strives to improve fuel efficiency by reducing vehicle mass and engine size. In addition antifreeze consumption is strongly influenced by consumer

spending patterns. In recessionary periods consumers tend to defer purchases of nondurable, discretionary goods such as antifreeze.

Figure 2. United States ethanediol-based antifreeze consumption

The manufacturing cost of ethanediol-based antifreeze is related directly to the cost of ethylene, presently the only commercially significant raw material for ethanediol. Table 4 shows the historic relationship between the market prices of ethanediol (industrial grade) and ethylene [21].

Table 4. Comparative prices of gaseous ethylene and ethanediol [21]

Year	Gaseous ethylene, average market price, U.S. Gulf Coast, ¢/kg	Industrial grade ethanediol, list price, delivered, U.S., ¢/kg
1973	7.3	19.8
1974	16.5	30.8
1976	26.0	51.8

Because ethanediol-based antifreeze is sold primarily as retail merchandise, the market pricing structure is highly fragmented, particularly in the United States domestic market. Pricing is influenced heavily by advertising, other merchandising techniques, and channels of distribution.

14. Toxicology and Occupational Health

The toxicity of antifreeze materials is an important consideration because of their widespread use [23]. The antifreeze base is normally the principal determinant of the toxicity; however, such antifreeze additives as anticorrosives and antioxidants also can contribute to their overall toxicity. For example, arsenic containing compounds previously were used as anticorrosives.

Handling *ethanediol-based antifreeze* or aqueous antifreeze solutions presents no unusual hazard. *External exposure* to ethanediol presents little hazard; neither skin nor eyes are affected adversely by occasional exposure. Prolonged skin exposure causes a slight macerating action, and the sensitivity of humans to this action is highly variable. Rubber gloves are advised for those handling antifreeze or antifreeze solutions frequently. Safety glasses, face shields, protective clothing, and general-purpose respiration equipment are also recommended.

The most serious hazard of ethanediol-based antifreeze is *oral ingestion.* The acute oral toxicity is relatively low for a variety of small animal species. For humans the lethal dosage by ingestion is approximately 100 mL in adults. The lethal dosage decreases with decreasing body weight.

Inhalation of mists or vapors of hot ethanediol is hazardous [23]. However, at ambient temperatures the vapor pressure of ethanediol is sufficiently low that inhalation risks are minimal.

The toxicity of *1,2-propanediol* to large animals and humans is significantly lower than that of ethanediol. The lethal dosage for adult humans is estimated to be in excess of 1 L. The effects of skin exposure to 1,2-propanediol are minimal, with the only concern being dehydration. 1,2-Propanediol is not an irritant to eyes nor does it cause tissue damage. Inhalation of vapors of 1,2-propanediol appears to cause no toxic effects.

1. Introduction

The *inflammatory response to injury* is a normal host defense mechanism that serves to isolate and remove the damage. Early events in this process include release of mediators, such as histamine and serotonin that dilate the blood vessels and increase their permeability. Subsequently, fluid leaking into the surrounding tissue space causes inflammation (i.e., swelling, pain, redness, and heat). Included in this fluid exudate are proteins, such as fibrinogen, which, when converted to fibrin, helps to seal off the affected area. Also present are polymorphonuclear neutrophils (PMNs) and leukocytes that phagocytize the infectious or toxic agent.

The inflammatory process is triggered by several interrelated cascade systems in the body. These include:

1) The complement system
2) The plasmakinin system
3) The clotting system
4) The arachidonic acid cascade

The *complement system* represents a cascade of approximately 25 serum proteins. The complement system mediates lysis of antibody-coated targets (bacteria, viruses, cells), recruits inflammatory cells to the sites of inflammation, and increases the efficiency of phagocytosis through opsonization.

Activation and interaction of the *clotting* and *plasmakinin systems* of the body also contribute to the inflammatory process (→ Blood, Chap. 2.2.). Activation of the Hageman factor (clotting factor XII), in addition to its effects on the coagulation system of the host, in turn activates the circulating protein, prekallikrein, to its enzymatically active form, kallikrein. The subsequent cleavage of another plasma substrate, kinonogen, by kallikrein liberates bradykinin, a linear nonapeptide. This peptide is a potent vasodilator that also has the ability to increase blood vessel permeability. In addition, bradykinin acts as a mediator of pain (elicits a pain response).

The *arachidonic acid cascade* has been the most actively studied of all the physiologic

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a03_033

components contributing to inflammation. Both cyclooxygenase and lipoxygenase pathway of arachidonic acid metabolism have been investigated for their effects on inflammation. Arachidonic acid is generated from cellular membrane phospholipids by the action of the enzyme phospholipase A_2. In the cyclooxygenase pathway, it is converted first to a short-lived endoperoxide and then to prostaglandins (→ Prostaglandins). In mammalian cells two cyclooxygenase (COX) enzymes exist which are encoded by different genes, but share a 60 % identity in amino acid sequence. COX-1 is constitutively expressed as a "housekeeping" enzyme in most tissues and mediates physiological responses such as regulation of renal and vascular homeostasis and cytoprotection of the stomach. In comparison, COX-2 is primarily considered as an inducible immediate-early gene product whose synthesis can be up-regulated by various proinflammatory agents, including endotoxin, cytokines, and mitogenes. COX-2 is the major isoform expressed by inflammatory cells and has, accordingly, been shown to release the high levels of prostanoids present under pathological conditions, such as acute and chronic inflammation [1]. The role of prostaglandins in inflammation is profound. Those of the E type increase blood vessel permeability and have the ability to sensitize various tissues (e.g., blood vessels, pain receptors) to the effects of other mediators, such as bradykinin.

The alternate pathway of arachidonic acid metabolism, the 5-lipoxygenase pathway, leads to the generation first of a hydroperoxide derivative, 5 HPETE, that stimulates histamine release from basophiles. Subsequent conversions lead to compounds known as leukotrienes that synergize with prostaglandins to cause increased blood vessel permeability and pain. One such leukotriene, LTB_4, is a potent chemotactic agent and a hyperalgesic agent (pain sensitizer) that shows additive effects with prostaglandins in pain mediation.

Much of the tissue destruction occurring during the inflammatory cycle can be attributed to substances released from the activated phagocytes that have been recruited to the site. These substances include free radicals and radical precursors, such as hydroxyl radicals and superoxide anion. Free radicals are nonspecific in their action and can cause destruction of membrane components, degradation of connective tissue, and depolymerization of hyaluronic acid leading to collagen damage. They may potentiate the action of proteolytic enzymes by oxidative destruction of naturally occurring inhibitors, such as α-1-proteinase inhibitor. In addition they feed the inflammatory cycle by further stimulation of leukocyte and macrophage functions.

Proteolytic enzymes, such as elastase and collagenase, are elaborated by PMNs at the inflammatory site either by active secretion or by death of the cell. Elastase is a neutral protease capable of degrading elastin and other connective tissue components, such as collagen, proteoglycan, and basement membrane. It may also interact with the complement and plasmakinin systems to liberate peptide mediators of inflammation, such as kinins, from soluble precursors. Collagenase catalyzes a specific cleavage of collagen and its precursor tropocollagen.

Furthermore, several *cytokines* (→ Blood, Chap. 2.1.3.) appear to play an essential role in the inflammatory process. Cytokines mediate effects induced by infectious agents, regulate lymphocyte growth, stimulate growth of precursor cell populations, and mediate inflammatory reactions. Interleukin (IL)-1 and tumor necrosis factor (TNF) possess very similar physiological actions in that both cytokines co-stimulate the process of antigen-induced activation of T cells, cause fever, and act on hepatocytes to induce the synthesis of plasma proteins, termed acute phase reactants. Under conditions of rheumatoid disease, IL-1 and TNF induce bone resorption by osteoclasts and increase proliferation of fibroblasts and synovial cells. Accordingly, increased levels of IL-1 and TNF have been detected in joint fluids from patients with rheumatoid arthritis. IL-6, which is produced by macrophages, monocytes, endothelial cells, and fibroblasts in response to IL-1 and TNF, stimulates the production of fibrinogen by hepatocytes and acts as a B cell growth factor. Other cytokines and growth factors contributing to the manifestation of the inflammatory response are IL-2, IL-8, and granulocyte-macrophage colony-stimulating factor (GM-CSF). Interestingly, some cytokines and growth factors possess anti-inflammatory activity (e.g., IL-10 and transforming factor (TGF)-β_1).

Despite the complexity and apparent propensity for endless self-perpetuation, most bouts of acute inflammation are self-limiting and result in

eventual resolution and healing. In some cases, however, persistent stimulation or immunologic derangement occurs, leading to a chronic and degenerative inflammation. Anti-inflammatory drugs are commonly used for these situations.

The most prevalent clinical inflammatory disorders are a variety of arthritic conditions, such as rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, gout, and systemic lupus erythematosus, which together affect about 7 % of the population worldwide.

Rheumatoid arthritis is a chronic inflammatory disease occurring in about 2 % of the population, with more women than men being affected. Most cases are relatively mild, and spontaneous remissions of the disease often occur. A minority of patients, however, develop severe and crippling deformities. Rheumatoid arthritis often affects peripheral joints, such as the knee, the wrist, and the fingers' proximal joints. The ankle, elbow, and hip may become involved but much less frequently. In rheumatoid arthritis, the membrane that lines the joint becomes inflamed and swollen, eventually covering and invading the cartilagenous surfaces of the joint. Progressive destruction of articular and periarticular structures follows, leading to loss of joint function.

The etiology of rheumatoid arthritis is largely unknown. One of the main characteristics of rheumatoid arthritis is an accumulation of T cells, plasma cells, macrophages, and fibroblast-like cells in inflamed joints. T lymphocytes specific for an unknown autoantigen have been suggested to play a crucial role in the induction and maintenance of synovial inflammation. However, the T cell centered hypothesis has been challenged by recent data showing that T cell targeted therapies were rather disappointing, particularly the use of anti-CD4 monoclonal antibodies.

Osteoarthritis, or degenerative joint disease, probably occurs as the result of chronic trauma or biomechanical stress. This disease also shows a predilection for certain joints, namely, the hip, the knee, and the fingers' distal joints. The elbow, shoulder, and ankle are rarely affected. Stress damage or simple "wear and tear" of the joint leads to chondrocyte (type of cartilage cell) damage and to the release of proteolytic enzymes that destroy the articular cartilage. The body's attempt to repair this damage causes formation of cartilagenous lumps that harden and become the osteophytes (bone knobs) characteristic of this disease.

Ankylosing spondylitis is a chronic and progressive inflammation that usually begins at the entheses (sites where muscle and tendon are joined to bone) of the sacroiliac joint and slowly spreads up the spinal column. Bony outgrowths gradually fuse one vertebral joint to the next, leading to restricted movement and eventual immobility of the spine. This disease occurs primarily in men, particularly those whose genetic make-up results in the presence of the HL-A W27 blood group antigen. Such individuals are approximately 600 times more likely to contract ankylosing spondylitis than those not carrying this antigen.

Gout is an arthritis of peripheral joints resulting from the deposition of sodium urate crystals in and about the joints and tendons. Ingestion of these crystals by PMNs results in the release of lysosomal enzymes that induce inflammation. Urate crystals can also activate the Hageman factor and the complement cascade. This condition is initially an acute problem, but repeated attacks lead to chronicity and deformation of the affected joints.

Systemic lupus erythematosus is an autoimmune disease of unknown origin resulting in a generalized inflammation of connective tissue throughout the body. It affects the joints, lungs, skin, heart, and kidneys and is primarily a disease of young women.

The anti-inflammatory drugs commonly used to treat the above conditions are generally divided into three classes:

1) Corticosteroids (→ Hormones)
2) Nonsteroidal anti-inflammatory – analgesic drugs (NSAIDs) and Selective COX-2 Inhibitors
3) Disease-modifying antirheumatic agents

2. Glucocorticoids

The glucocorticoids are oxygenated pregnenes bearing an α-ketol side chain at position 17. They include the natural adrenal cortical hormones, cortisol and cortisone, as well as a host of synthetic analogs. The potent and dramatic

anti-inflammatory effect of cortisone was first demonstrated in rheumatoid arthritic patients in 1948 and thus began a new era of antiarthritic therapy. In addition corticosteroids also are used to treat dermatitis and often preserve sight when used for ocular inflammation.

Molecular-biological studies performed in the 1990s have provided new insights into the mode of action of glucocorticoids in controlling inflammation. Glucocorticoids bind to a cytoplasmic receptor within the target cells thus inducing a rapid nuclear translocation of the activated glucocorticoid receptor-steroid complex into the nucleus. After binding to DNA at consensus sites (i.e., glucocorticoid response elements) in the promoter region of glucocorticoid-responsive genes glucocorticoids can either increase or decrease transcription of numerous genes involved in inflammatory reaction. Furthermore, glucocorticoid receptors directly interact with transcription factors activated under chronic inflammatory conditions. Accordingly, glucocorticoid receptor complexes inhibit the activated form of nuclear factor κB (NF-κB) via a direct protein-protein interaction thereby repressing gene transcription. As NF-κB induces many inflammatory genes encoding cytokines, chemokines, adhesion molcules, and the inflammatory enzymes inducible nitric oxide synthase (iNOS) and COX-2, the inactivation of activated NF-κB in the nucleus represents an important effect of glucocorticoids in repressing gene transcription of various proinflammatory mediators [2], [3].

The use of glucocorticoids is accompanied by serious *adverse effects.* Changes are seen in the metabolism of carbohydrate (increased gluconeogenesis and hyperglycemia), of protein (increased catabolism and negative nitrogen balance), and of fat (increased synthesis and deposition). Disturbances in mineral balance include sodium retention, potassium depletion, and loss of bone calcium. Effects on the CNS range from euphoria to mania. Finally, suppression of endocrine function, particularly of the pituitary and hypothalamus, occurs.

Glucocorticoids used for systemic or local anti-inflammatory activity include hydrocortisone, cortisone acetate, prednisolone, dexamethasone, betamethasone, and triamcinolone. Derivatization provides injectable compounds having a rapid onset of action. For this purpose, esters of the 21-hydroxy group with phosphoric or succinic acid are used as their sodium salts. Depot forms of glucocorticoid drugs can be obtained by preparing slowly hydrolyzable esters of the 21-hydroxy group with hindered acids, such as pivalic or *tert*-butylacetic acid.

Glucocorticoids used extensively for topical administration include hydrocortisone acetate, betamethasone acetate, and triamcinolone acetonide.

For structure, properties, and preparation → Hormones.

3. Nonsteroidal Anti-inflammatory Drugs and Selective COX-2 Inhibitors

Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit the activity of COX which catalyzes the synthesis of prostanoids by converting arachidonic acid and molecular oxygen into prostaglandin H_2, the common substrate for specific prostaglandin synthases [4]. Most of the NSAIDs inhibit both COX-1 and COX-2 at therapeutic doses, although they vary in their relative potencies against the two isozymes [5]. Whereas the mechanism-based side effects of NSAIDs (e.g., gastrointestinal toxicity, platelet dysfunctions) are due to a suppression of COX-1-derived prostanoids, compelling evidence suggests that inhibition of prostanoids produced by COX-2 can be ascribed to the anti-inflammatory, analgesic, and antipyretic effects of NSAIDs. Accordingly, treatment with NSAIDs with a higher affinity to the COX-1 isozyme (e.g., piroxicam, sulindac) results in increased gastrointestinal adverse reactions. Specific COX-2 inhibitors are expected to exert anti-inflammatory and analgesic effects without causing gastric ulcerogenic effects or platelet dysfunction. *Per definitionem*, a substance may be regarded as a specific COX-2 inhibitor if it causes no clinically meaningful COX-1 inhibition at maximal therapeutic doses. Such compounds usually reveal a more than 100-fold difference in the concentration that inhibits recombinant COX-2 versus COX-1 in respective biochemical in vitro assays [6]. X-ray crystallographic studies of the three-dimensional structures of COX-1 and COX-2 have provided more insight into how COX-2

specificity is achieved. Within the hydrophobic channel of the COX enzyme, a single amino acid difference in position 523 (isoleucin in COX-1, valin in COX-2) has been detected, that is critical for the COX-2 selectivity of several drugs. Accordingly, the smaller valin molecule in COX-2 gives access to a "side pocket", which has been proposed to be the binding site of COX-2 selective substances. Consequently, the total NSAID-binding site is about 25 % larger in COX-2 than in COX-1 [7]. Thus, the increased NSAID-binding pocket of the COX-2 isozyme can bind bulky inhibitors more readily than the COX-1 isoform. Celecoxib (SC58635) and rofecoxib (MK-966) are novel selective COX-2 inhibitors of the diarylheterocyclic family (see Section 3.8). The 4-methylsulfonylphenyl and 4-sulfonamoylphenyl groups of these compounds have been shown to interact with specific residues within the "side pocket" of the COX-2 isozyme. Both compounds have been shown to be effective analgesics in dental pain models, and effective anti-inflammatory and analgesic substances in patients with rheumatoid arthritis and osteoarthritis [8]. Celecoxib and rofecoxib have been associated with fewer adverse gastrointestinal effects than traditional NSAIDs. The first selective COX-2 inhibitor, celecoxib (SC58635) was approved in December 1998 by the U.S. Food and Drug Administration for rheumatoid arthritis and osteoarthritis. Rofecoxib became available in 1999 for the indications osteoarthritis and pain. COX-2 is also expressed under basal conditions in organs such as the ovary, uterus, brain, spinal cord, kidney, cartilage, and bone, suggesting that this isozyme may play a more complex physiological role than formerly expected. Accordingly, COX-2 may be implicated in physiological processes such as ovulation [9] and delivery [10], [11]. Moreover, COX-2 is induced in tissue on the edges of ulcers, and in animals studies selective COX-2 inhibitors have been shown to retard ulcer healing [12]. Thus, in patients with NSAID-associated ulcers, it will be obligatory to show whether effective ulcer healing occurs in those patients that switched to treatment with selective COX-2 inhibitors. Controlled clinical trials will gain insights into other possible side effects of selective COX-2 inhibitors in humans. On the other hand, the involvement of the COX-2 isozyme in pathological states suggests that selective COX-2 inhibitors may have further indications in conditions such as colonic polyposis, colorectal cancer, and Alzheimer's disease.

3.1. Salicylates

The therapeutic use of salicylates, in the form of extracts of willow bark, for an antipyretic effect dates back to early civilization. Elucidation of the chemical structure of the active ingredient, salicin, led to the use of sodium salicylate for the treatment of both rheumatic fever and gout in the 1870s. This was followed by the introduction of the less irritating *O*-acetyl derivative of salicylic acid, aspirin, in 1899. Acetylsalicylic acid served for many years as the cornerstone in the therapy of rheumatoid disease, being the safest, least expensive yet effective agent available. This efficacy is now attributed to the ability of aspirin to irreversibly inhibit arachidonic acid cyclooxygenase by transacetylation of this enzyme. However, the theory that suppression of prostaglandin biosynthesis accounts for the pharmacological actions and the side effects of NSAIDs has been questioned by comparing the actions of salicylate and aspirin [13]. Salicylate, being used as an NSAID for more than one century now, does not, unlike aspirin, inhibit COX-1 and COX-2 activity in vitro [5], [14]. However, despite lacking inhibitory activity against purified COX-1 or COX-2, salicylate exerts comparable anti-inflammatory properties as aspirin [15], and has considerable inhibitory effects on prostaglandin synthesis in intact cells [5], [16], [17] as well as in vivo [18] and ex vivo [19] at sites of inflammation. Several suggestions have been made to describe how salicylates exert their anti-inflammatory and side effects. One proposal is that salicylates act by inhibition of the transcription factor NF-κB [20]. However, relatively high concentrations of sodium salicylate (i.e., higher than that obtained after therapeutic doses) were required to provide significant effects. In 1997 is was demonstrated that sodium salicylate is an effective inhibitor of COX-2 activity at concentrations far below those required to inhibit NF-κB activation and it has been suggested that aspirin and sodium salicylate exerts their pharmacological effects via a weak competitive inhibition with arachidonic acid in the

active site of the enzyme, rather than via inhibition of NF-κB activation. Furthermore, in IL-1β-stimulated endothelial cells sodium salicylate was shown to inhibit COX-2 expression at pharmacological concentrations [16]. However, these results could not be reproduced in other studies [17], [21], [22], [23] despite the fact that much higher salicylate concentrations were investigated.

Years of chemical effort to modify the salicylic acid molecule in order to find a safer and more effective derivative have yielded only a few therapeutically useful salicylates. Newer salicylic acid derivatives such as trilisate, benorylate, and chlorthenoxazine are available for use primarily as acute analgesic – antipyretic agents. Diflunisal with a biphenyl structure is a salicylate analog possessing greater potency, better tolerance, and longer duration of action in anti-inflammatory and analgesic studies.

For the structure and syntheses of acetylsalicylic acid, benorylate, and diflunisal, → Analgesics and Antipyretics.

Acetylsalicylic Acid [*50-78-2*], 2-(acetyloxy)benzoic acid, aspirin, $C_9H_8O_4$, M_r 180.15, *mp* 135 °C.

Trade names: Acetylin (Bristol Myers Squibb, Germany), Acimetten (Pharmonta, Austria), Adprin (Pfeiffer, USA), Alka Seltzer (Bayer, Austria, Switzerland, Czech Republic), Angettes (Bristol-Myers, UK), Asaped (Sanofi-Winthrop, USA), Aspirin (Bayer, Germany), Aspro (Roche Nicholas, Germany), Colfarit (Bayer Pharma Deutschland, Germany), Zorprin (Knoll, USA).

Benorylate [*5003-48-5*], 4-acetamidophenyl 2-acetoxybenzoate, $C_{17}H_{15}NO_5$, M_r 313.32, *mp* 175 – 176 °C.

Trade names: Benoral (Sterling-Winthrop, UK), Benortan (Winthrop, The Netherlands), Duvium (Inpharzam, Belgium, Switzerland), Longalgic (Evans Medical, France), Salipran (Evans Medical, France), Spierifex (Winthrop, The Netherlands).

Benorylate is the acetaminophen ester of acetylsalicylic acid, designed to provide a less irritating form of aspirin. Gastrointestinal blood loss in patients taking benorylate is less than that during therapy with soluble aspirin. Benorylate has been found to be as effective as aspirin for the treatment of chronic rheumatic disorders.

Diflunisal [*22494-42-4*], 2′,4′-difluoro-4-hydroxy-(1,1′-biphenyl)-3-carboxylicacid, $C_{13}H_8F_2O_3$, M_r 250.20, *mp* 210 – 211 °C.

Trade names: Biartac (Merck Sharp & Dohme, Belgium), Diflonid (Dumex, Denmark, Sweden), Diflusal (Merck Sharp & Dohme, Belgium), Dolobid (Frosst, Canada; Logos, South Africa; Merck, USA; Morson, UK), Dolobis (M.S.D.-Chibret, France), Fluniget (Merck Sharp & Dohme, Austria).

Diflunisal is a salicylate with greater anti-inflammatory and analgesic potency and with a long plasma half-life that allows for twice-a-day dosage. Without an *O*-acetyl group it is a reversible inhibitor of cyclooxygenase. It is comparable in efficacy to aspirin in the treatment of osteoarthritis and rheumatoid arthritis but is much better tolerated.

3.2. Arylacetic Acids

Indomethacin [*53-86-1*], 1-(4-chlorobenzoyl)-5-methoxy-2-methyl-1*H*-indole-3-acetic acid, $C_{19}H_{16}ClNO_4$, M_r 357.81, *mp* 155 °C or 162 °C depending on crystal form.

Synthesis: acylation of sodium 2-(4-methoxyphenyl)hydrazine-1-sulfonate with 4-chlorobenzoyl chloride followed by heating yields 1-(4- chlorobenzoyl)-1-(4-methoxyphenyl)hydrazine. Condensation with levulinic acid in a Fischer indole synthesis affords indomethacin [24].

The introduction of indomethacin in 1963 represented a milestone in the therapy of rheumatic diseases. For 20 years this drug has served as the clinical standard against which new NSAIDs are evaluated. It has also been a valuable biochemical – pharmacological tool in the study of the inflammatory process. It is a potent inhibitor of prostaglandin biosynthesis.

Clinically it is indicated for the treatment of rheumatoid arthritis, ankylosing spondylitis, osteoarthritis, and gout. Its potency as an anti-inflammatory, analgesic, antipyretic agent is counterbalanced by accompanying adverse effects, the most common of which are gastrointestinal irritation and headache.

Trade names: Amuno (MSD Sharp & Dohme, Germany), Arthrexin (Lennon Generics, South Africa), Confortid (Dumex, Denmark, Sweden, Finland), Doctucid (Coctum, Greece), Dynamectin (Dynamed, South Africa), Flexidin (Mundipharma, Austria), Inacid (Merck Sharp & Dohme, Spain), Indobene (Merckle, Austria, CIS), Indocin (Merck, USA), Reumadolor (Bros, Greece), Zoflam (Norpharma, Denmark).

Attempts to develop a safer indomethacin have led to the introduction of the following four derivatives.

Indomethacin

Acemetacin [*53164-05-9*], {[1-(4-chlorobenzoyl)-5-methoxy-2-methylindol-3-yl]acetoxy}-acetic acid, $C_{21}H_{18}ClNO_6$, M_r 415.60, *mp* 149.5 – 150.5 °C

Synthesis: alkylation of indomethacin with benzyl bromoacetate in K_2CO_3/*N,N*-dimethylformamide gives the corresponding benzyl glycolate ester, which is hydrogenated over 10 % palladium on charcoal in acetic acid to yield acemetacin [25].

Acemetacin is used in the treatment of pain and restricted mobility resulting from chronic articular rheumatism, degenerative articular disease, gout, and inflammation of muscle, joints, and tendons. Acemetacin causes less gastrointestinal blood loss than indomethacin. Its anti-inflammatory activity results from liberation of the parent compound, indomethacin.

Acemetacin

Trade names: Acemetacin (Heumann, Stada, Germany), Acemix (Bioprogress, Italy), Altren (Rhône-Poulenc Rorer, Belgium), Emflex (Merck, UK), Rantudil (Bayer Pharma Deutschland, Germany).

Glucametacin [*52443-21-7*], 2-({[1-(4-chlorobenzoyl)-5-methoxy-2-methyl-1*H*-indol-3-yl]acetyl}amino)−2-deoxy-D-glucose, $C_{25}H_{27}ClN_2O_8$, M_r 518.96, *mp* 218 °C decomp.

Synthesis: glucametacin is prepared by acylation of D-glucosamine with indomethacin acid chloride (prepared from indomethacin and thionyl chloride) in the presence of sodium hydroxide [26].

Glucametacin

Glucametacin is used to treat inflammatory and degenerative arthropathy. The compound is well tolerated with significantly less gastrointestinal distress than indomethacin. Glucametacin does not appear to be metabolized to indomethacin.

Trade names: Euminex (Asta Medica, Spain), Teoremin (Labofarma/Degussa, Brazil).

Oxametacine [*27035-30-9*], 1-(4-chlorobenzoyl)-*N*-hydroxy-5-methoxy-2-methyl-1*H*-indole-3-acetamide, $C_{19}H_{17}ClN_2O_4$, M_r 372.81, *mp* 181 – 182 °C

Synthesis: oxametacine is prepared by the acylation of hydroxylamine with indomethacin acid chloride [27].

Oxametacin

Oxametacine at a dose of 100 mg is reported to be as effective as 50 mg of indomethacin in reducing pain and inflammation with a lower incidence of adverse effects.

Trade names: Flogar (UCB, Belgium; ABC, Portugal).

Proglumetacin maleate [*59209-40-4*], *N*-{2-[1-(4-chlorobenzoyl)–5-methoxy-2-methyl-3-indolylacetoxy]ethyl}-*N′*-[3-(*N*-benzoyl-*N′*,*N′*-di*n*-propyl-DL-isoglutaminyl)oxypropyl]piperazine (±)-dimaleate, $C_{46}H_{58}ClN_5O_8 \cdot 2\,C_4H_4O_4$, M_r 1075.98, *mp* 146 – 148 °C.

Synthesis: alkylation of the anticholinergic agent proglumide with *N*-(3-chloropropyl)-*N′*-(2-hydroxyethyl)piperazine using sodium methoxide in dimethyl sulfoxide gives *N*-[3-(*N*-benzoyl-*N′*,*N′*-di-*n*-propyl-DL-isoglutaminyl)oxypropyl]-*N′*-(2-hydroxyethyl)piperazine, which is then condensed with indomethacin using dicyclohexylcarbodiimide. The resulting ester is treated with maleic acid to give proglumetacin maleate [28].

Proglumetacin at a dose of 450 mg/d appears to be as effective as 150 mg/d of indomethacin in the treatment of a wide variety of rheumatic conditions, and is faster acting with significantly lower incidence and severity of adverse effects. It is metabolized to several derivatives, including indomethacin, in humans.

Trade names: Afloxan (Rotta Research, Italy), Protaxil (Rottapharm, Spain), Protaxon (Opfermann, Germany), Proxil (Rottapharm, Italy), Tolindol (La Meuse, Belgium).

Sulindac [*38194-50-2*], (*Z*)-5-fluoro-2-methyl-1-{[4-(methylsulfinyl)phenyl]-methylene}-1*H*-indene-3-acetic acid, $C_{20}H_{17}FO_3S$, M_r 356.42, *mp* 182 – 185 °C (decomp.).

Synthesis: Friedel – Crafts reaction of fluorobenzene and α-bromoisobutyryl bromide gives 5-fluoro-2-methylindan-1-one, which is treated with 4-methylthiobenzylmagnesium chloride to yield 5-fluoro-2-methyl-1-(4-methylthiobenzyl)indene. Condensation with glyoxylic acid in the presence of *N*-benzyltrimethylammonium hydroxide (Triton B) gives 3-carboxymethylene-5-fluoro-2-methyl-1-(4-methylthiobenzyl)indene, which is isomerized in acid to 5-fluoro-2-methyl-1-(4-methylthiobenzylidene)indene-3-acetic acid. Oxidation with hydrogen peroxide affords sulindac [29], [30].

Sulindac is an indene isostere of indomethacin and is a reversible prodrug. Its anti-inflammatory activity depends on metabolic conversion to the corresponding sulfide. The long serum half-life of the sulfide metabolite allows it to be given only once or twice a day. Sulindac is much better tolerated than indomethacin in all five of its indications: rheumatoid arthritis, osteoarthritis, gout, ankylosing spondylitis, and acute painful shoulder. There is a low incidence of adverse effects, consisting chiefly of gastrointestinal disturbances.

Trade names: Aflodac (Biotekfarma, Italy), Algocetil (Francia Farm., Italy), Clinoril (Frosst, The Netherlands; Merck Sharp & Dohme, Aus-

tria, Belgium, Denmark, UK, Slovacian republic); Dorindac (Chibret, Portugal), Zirofalen (Farmalen, Greece).

Sulindac

Tolmetin [*26171-23-3*] 1-methyl-5-(4-methylbenzoyl)-1*H*-pyrrole-2-acetic acid, $C_{15}H_{15}NO_3$, M_r 257.30, *mp* 155 – 157 °C.

Synthesis: Friedel – Crafts acylation (aluminum chloride – carbon disulfide) of ethyl 1-methyl-1*H*-pyrrole-2-acetate with 4-toluyl chloride gives ethyl 1-methyl-5-(4-methylbenzoyl)-1*H*-pyrrole-2-acetate, which on saponification yields tolmetin [31].

Tolmetin is an anti-inflammatory, analgesic – antipyretic agent indicated for acute and long-term treatment of rheumatoid arthritis. Its activity is comparable to aspirin and indomethacin, but it causes fewer and milder gastrointestinal disturbances than the former and fewer CNS disturbances than the latter. Other adverse effects include dizziness, tinnitus, edema, and rash. It is administered as its sodium salt dihydrate.

Trade names: Artrocaptin (Estedi, Spain), Tolectin (Cilag, Belgium; Janssen-Cilag, Austria; McNeil, USA).

Metiazinic acid [*13993-65-2*], 10-methylphenothiazine-2-aceticacid, $C_{15}H_{13}NO_2S$, M_r 271.34, *mp* 146 °C.

Synthesis: metiazinic acid is prepared via the Willgerodt reaction (sulfur and morpholine) from 2-acetyl-10-methylphenothiazine [32].

Tolmetin

Metiazinic acid

Metiazinic acid has been beneficial to arthritis patients when given at a daily dose of 0.75 – 1.5 g/d.

Trade names: Roimal (Kantoishi, Japan), Soripal (Torii, Japan).

Alclofenac [*22131-79-9*], 3-chloro-4-(2-propenyloxy)benzeneacetic acid, $C_{11}H_{11}ClO_3$, M_r 226.66, *mp* 92 – 93 °C.

Synthesis: alkylation of ethyl 3-chloro-4-hydroxyphenylacetate with allyl bromide in acetone containing potassium carbonate followed by saponification of the ester group gives the product [33].

Alclofenac when used at 3 g/d in the treatment of rheumatoid arthritis is as effective as 75 mg/d of indomethacin with fewer adverse effects. In the treatment of osteoarthritis 1500 mg/d is as effective and is better tolerated than 300 mg/d of phenylbutazone. Alclofenac has been withdrawn from the market

in the United Kingdom because of skin rash and vasculitis (blood vessel inflammation).

Trade names: Mervan (Continental, Belgium).

Alclofenac

Diclofenac sodium [*15307-79-6*], 2-[(2,6-dichlorophenyl)amino]benzeneaceticacid monosodium salt, $C_{14}H_{10}Cl_2NNaO_2$, M_r 282.68, *mp* 283 – 285 °C.

Synthesis: acylation of *N*-phenyl-2,6-dichloroaniline with chloroacetyl chloride gives the corresponding chloroacetanilide, which is fused with aluminum chloride to give 1-(2,6-dichlorophenyl)-2-indolinone. Hydrolysis of the indolinone with dilute aqueous-alcoholic sodium hydroxide affords the desired sodium salt directly [34].

Diclofenac sodium

The structure of diclofenac is a hybrid of a fenamate and an arylacetic acid. The compound is used as its sodium salt for the symptomatic relief of rheumatoid arthritis and osteoarthritis, including degenerative joint disease of the hip. The recommended dose is 75 – 150 mg/d which is clinically equivalent to 3.6 g/d of aspirin. Gastrointestinal problems (ulceration and bleeding) and adverse CNS reactions (dizziness and headache) are the most commonly encountered adverse effects (for review see [35]).

Trade names: Arthrex (BASF GENERICS, Germany), Benfofen (Sanofi Winthrop, Germany), Diclac (Hexal, Germany), Diclobene (Merckle, CIS, Austria), Diclophlogont (Azupharma, Germany), Diclosifar (Siphar, Switzerland), Dolgit (Dolorgiet, Germany), Rewodina (Asta Medica AWD, Germany), Voltaren (Novartis Pharma, Germany), Arthrotec (Searle, UK, Italy).

Fentiazac [*18046-21-4*], 4-(4-chlorophenyl)- 2-phenyl-5-thiazoleaceticacid, $C_{17}H_{12}ClNO_2S$, M_r 329.81, *mp* 161 – 162 °C.

Synthesis: refluxing a mixture of 3-bromo-3-(4-chlorobenzoyl)propionic acid and thiobenzamide in ethanol gives ethyl 2-phenyl-4-(4-chlorophenyl)thiazole-5-acetate, which is then saponified to yield fentiazac [36].

Fentiazac

Fentiazac is reported to have anti-inflammatory, analgesic, and antipyretic activity. It has been given once or twice a day at levels between 100 and 200 mg/dose in the treatment of postoperative pain, including that following orthopedic surgery. The most common adverse effect is gastrointestinal intolerance, including epigastric pain, nausea, and vomiting. Effects on the CNS, such as headache and dizziness, also have been reported.

Trade names: Atilan (Zambon, Brazil), Donorest (Fontoura-Wyeth, Brazil), Flogene (Polifarma, Italy), Norvedan (Boehringer Mannheim, Austria; LPB, Italy).

3.3. Arylacetic Acid Prodrugs

Metabolic precursors to arylacetic acids have been introduced into rheumatoid therapy in the form of 4-aryl-4-oxobutyric acids. ω-Phenyl fatty acids undergo normal two-carbon degradation of the side chain to give either benzoic or phenylacetic acids depending on the number of carbon atoms in the original molecule. Therefore, ω-phenyl-γ-oxoacids were presumed to behave similarly; e.g., 4-phenyl-4-oxobutyric and

6-phenyl-4-oxo-hexanoic acid are degraded in vivo to phenylacetic acid.

The oxoacids are not very potent inhibitors of cyclooxygenase and their in vivo activity is probably dependent on metabolic conversion to the corresponding phenylacetic acid.

Fenbufen [*36330-85-5*], γ-oxo(1,1′biphenyl)-4-butanoic acid, $C_{16}H_{14}O_3$, M_r 254.29, *mp* 185 – 187 °C.

Synthesis: Fenbufen is prepared by the Friedel-Crafts (aluminum chloride – nitrobenzene) acylation of biphenyl with succinic anhydride [37].

Fenbufen

Fenbufen has been found to be an effective, well-tolerated drug for the treatment of rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis. The compound is metabolized in humans first to 4-hydroxy-4-biphenylbutyric acid (t_{max} 2.5 h) then to 4-biphenyl acetic acid (t_{max} 7.5 h). Both metabolites are more active than fenbufen itself and circulate for several hours ($t_{1/2}$ 10 h). This slow conversion of fenbufen to active metabolites having relatively long plasma half-lives allows for once a day dosing with this agent.

Trade names: Clincopal (Lederle, Spain), Lederfen (Lederle, UK), Napanol (Lederle, Japan).

3.4. Arylpropionic Acids

Ibuprofen [*15687-27-1*], α-methyl-4-(2-methylpropyl)benzeneaceticacid, $C_{13}H_{18}O_2$, M_r 206.27, *mp* 75 – 77 °C.

Synthesis: treatment of ethyl 4-isobutylphenylacetate and diethyl carbonate with sodium ethoxide gives diethyl 4-isobutylphenylmalonate, which is methylated using methyl iodide and sodium ethoxide. Saponification followed by decarboxylation of the resulting malonic acid derivative affords ibuprofen [38].

Ibuprofen is indicated for both acute and long-term management of rheumatoid arthritis, osteoarthritis, and psoriatic arthritis. Anti-inflammatory efficacy depends on relatively high dosage, 2.4 g/d. The drug is well tolerated, the chief adverse effect being a low incidence of gastrointestinal disturbance. The drug is rapidly absorbed and eliminated with a serum half-life of about 2 h. Ibuprofen does not interfere with the protein binding of warfarin and can be used safely in patients undergoing anticoagulant therapy. It is available as a nonprescription drug.

Trade names: Advil (Whitehall, USA; Whitehall-Robins, Canada); Aktren (Bayer Selbstmed, Germany), Algifor (Vifor, Switzerland), Ardinex (Boots, Finland), Brufen (Boots, Portugal; Knoll, Belgium), Dismenol (Merz Consumer Division, Germany), Dolgit (Dolorgiet, Germany), Dolo-Puren (Isis Puren, Germany), Dolormin (Woelm, Germany), Duafen (Pharmed, Austria), Haltran (Upjohn, USA), Ibufen (Amino, Switzerland), Ibunet (Nettopharma, Denmark), Rufen (Knoll, USA).

Naproxen [*22204-53-1*], (+)-6-methoxy-α-methyl-2-naphthaleneaceticacid, $C_{14}H_{14}O_3$, M_r 230.26, *mp* 155.3 °C, $[\alpha]_D$ +65.5° (*c* 1.0, $CHCl_3$).

Synthesis: Friedel - Crafts acylation (aluminum chloride - nitrobenzene) of β-naphthol methyl ether affords 2-acetyl-6-methoxynaphthalene, which, when treated with either dimethylsulfonium or dimethylsulfoxonium methylide, gives 2-(6-methoxynaphthalen-2-yl)propylene oxide. Treatment

of the latter with boron trifluoride etherate in tetrahydrofuran gives 2-(6-methoxynaphthalen-2-yl)propionaldehyde, which is oxidized using Jones reagent (4 M chromic acid) to yield the racemic 2-(6-methoxynaphthalen-2-yl)propionic acid. Resolution and isolation of the dextrorotatory enantiomer is accomplished via its cinchonidine salt [39].

Naproxen

Naproxen is used in the treatment of rheumatoid arthritis, osteoarthritis, gout, and ankylosing spondylitis at a daily dose of 500 – 700 mg. Absorption from the gastrointestinal tract is virtually complete, and extensive binding (99 %) to serum albumin provides for a relatively long plasma half-life (13 h) and twice-a-day dosing. Naproxen is reasonably well-tolerated with gastrointestinal disturbances being the principal adverse effect. Its more rapidly absorbed sodium salt is marketed as an analgesic providing earlier pain relief.

Trade names: Anaprox (Syntex, Canada, USA), Apranax (Roche, France), Bonyl (Ercopharm, Denmark), Miranax (Syntex, Finland), Novo-Naprox (Novorpharm, Canada), Proxen (Hoffmann La Roche, Germany).

Ketoprofen [*22071-15-4*], 3-benzoyl-α-methylbenzeneaceticacid, $C_{16}H_{14}O_3$, M_r 254.29, *mp* 94 °C.

Synthesis: bromination (bromine – ultraviolet light) of 3-methylbenzophenone and nucleophilic substitution of the resulting bromomethyl compound with sodium cyanide gives 3-benzoylphenylacetonitrile. Treatment with diethyl carbonate and sodium ethoxide followed by alkylation of the resulting 2-cyano ester gives ethyl 2-(3-benzoylphenyl)-2-cyanopropionate. Acid hydrolysis and decarboxylation yields ketoprofen [40].

Ketoprofen

Ketoprofen is indicated in the treatment of rheumatoid arthritis, ankylosing spondylitis, and osteoarthritis at a daily dose of 150 – 300 mg. At 150 mg/d its clinical efficacy is comparable to a similar dose of indomethacin, but fewer and less severe adverse effects are observed.

Trade names: Alrheumat (Bayer, United Kingdom), Alrheumun (Bayer Pharma Deutschland, Germany), Gabrilen (Kreussler, Germany), Orudis (Rhône-Poulenc Rorer, Canada, Denmark; Wyeth-Ayerst, USA).

Fenoprofen [*31879-05-7*], α-methyl-3-phenoxybenzeneaceticacid, $C_{15}H_{14}O_3$, M_r 242.28, *bp* 168 – 171 °C (0.015 kPa).

Synthesis: sodium borohydride reduction of 3-phenoxyacetophenone followed by bromination of the resulting alcohol with PBr_3 gives α-methyl-3-phenoxybenzyl bromide. Reaction of this bromide with sodium cyanide in dimethyl sulfoxide gives the corresponding nitrile, which is hydrolyzed using sodium hydroxide. Acidification affords fenoprofen [41].

Fenoprofen

Fenoprofen is used as its calcium salt dihydrate in the treatment of rheumatoid arthritis and osteoarthritis at a daily dose of 1.2 – 3.0 g. The drug is rapidly absorbed and excreted with a plasma half-life of about 3 h despite being extensively bound (99 %) to plasma protein. Fenoprofen is well tolerated, with dyspepsia being the chief adverse effect.

Trade names: Fenopron (Lilly, South Africa, United Kingdom), Fepron (Lilly, Italy), Nalfon (Dista, USA, Austria, Canada), Nalgesic (Lilly, France), Progesic (Lilly, United Kingdom).

Flurbiprofen [*5104-49-4*], 2-fluoro-α-methyl(1,1′-biphenyl)-4-aceticacid, $C_{15}H_{13}FO_2$, M_r 244.27, *mp* 110 – 111 °C.

Synthesis: ethyl 2-fluoro-4-biphenylacetate, prepared from 4-acetyl-2-fluorobiphenyl via the Willgerodt reaction and subsequent esterification, is treated first with diethyl carbonate and sodium ethoxide, then with dimethyl sulfate to give diethyl 2-(2-fluoro-4-biphenylyl)-2-methyl malonate. Saponification followed by acidification affords the malonic acid, which is decarboxylated at 180 – 200 °C to yield flurbiprofen [42].

Flurbiprofen has been used at 150 – 300 mg/d in the treatment of rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis. Gastrointestinal disturbances, particularly dyspepsia, are the principal adverse effects.

Trade names: Ansaid (Pharmacia & Upjohn, CIS; Upjohn, Canada, Czech Republic, Poland, USA), Cebutid (Knoll, France), Froben (Kanoldt, Germany; Ebewe, Austria; Boots, Spain, The Netherlands, Portugal), Tulip (Upjohn, Spain).

Flurbiprofen

Clidanac [*34148-01-1*], 6-chloro-5-cyclohexyl-2,3-dihydro-1*H*-indene-1-carboxylic acid, $C_{16}H_{19}ClO_2$, M_r 278.78, *mp* 150.5 – 152.5 °C.

Synthesis: formylation of cyclohexylbenzene using dichloromethyl methyl ether and titanium tetrachloride gives 4-cyclohexylbenzaldehyde, which is condensed with diethyl malonate to yield diethyl 4-cyclohexylbenzylidenemalonate. Treatment of the latter with potassium cyanide in ethanol at 70 °C gives ethyl 3-cyano-3-(4-cyclohexylphenyl)propionate, which is converted to 4-cyclohexylphenylsuccinic anhydride following acid hydrolysis and treatment with refluxing acetic anhydride. An intramolecular Friedel – Crafts acylation (aluminum chloride – methylene chloride) affords 5-cyclohexyl-3-oxo-1-indanecarboxylic acid, which is catalytically reduced using 10 % palladium on charcoal in the presence of perchloric acid to give 5-cyclohexyl-1-indanecarboxylic acid. Chlorination using *N*-chlorosuccinimide in *N*,*N*-dimethylformamide (DMF) gives clidenac [43].

Clidenac is used for the relief of pain and inflammation related to arthrosis deformans, periarthritis humeroscapularis, cervical syndrome, and lumbago.

Trade names: Britai (Bristol Banyu, Japan), Indanal (Takeda, Japan).

Clidanac

Pirprofen [*31793-07-4*], 3-chloro-4-(2,5-dihydro-1*H*-pyrrol-1-yl)-α-methylbenzeneacetic acid, $C_{13}H_{14}ClNO_2$, M_r 251.71, *mp* 98 – 100 °C.

Synthesis: treatment of the sodium salt of diethyl methylmalonate with 2,4-dichloronitrobenzene yields diethyl (3-chloro-4-nitrophenyl)methylmalonate. Saponification, decarboxylation, and subsequent reesterification followed by catalytic reduction gives ethyl 4-amino-3-chloro-α-methylbenzeneacetate hydrochloride. Treatment of the latter with 1,4-dichloro-2-butene in the presence of sodium carbonate followed by saponification affords pirprofen [44].

Pirprofen

Pirprofen has been used to treat rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis. An optimal dosing regimen of 200 mg three times a day has been developed for maximal activity with minimal adverse effects. Pirprofen also is effective in relieving pain from malignant disease and oral surgery.

Trade name: Rengasil (Ciba, Greece), Seflenyl (Geigy, Argentina).

3.5. Acidic Enolic Compounds

Phenylbutazone [*50-33-9*], 4-*n*-butyl-1,2-diphenyl-3,5-pyrazolidinedione, $C_{19}H_{20}N_2O_2$, M_r 308.37, *mp* 105 °C.

Synthesis: heating diethyl-*n*-butylmalonate and 1,2-diphenylhydrazine in the presence of sodium ethoxide at 150 °C followed by acidification affords phenylbutazone in good yield. Alternatively, *n*-butylmalonyl chloride in pyridine and ether at 0 °C is treated with 1,2-diphenylhydrazine to give the desired product [45].

Phenylbutazone

Phenylbutazone, one of the earliest NSAIDs introduced, is now indicated for the symptomatic relief of rheumatoid arthritis, osteoarthritis, psoriatic arthritis, ankylosing spondylitis, gout, and acute superficial thrombophlebitis.

The gastrointestinal and bone marrow toxicity observed in its early use have been greatly reduced by lower dosage (300 mg/d). Nevertheless, it is used primarily where other drugs have failed and then only for short-term therapy. The drug has a long serum half-life of about 100 h. It is a moderately active cyclooxygenase inhibitor and it suppresses both spontaneous and chemotactic motility of neutrophils. In addition to the serious gastrointestinal and hematological adverse effects, sodium and water retention, rash, vertigo, and dermatitis are observed.

Trade names: Ambene (Merckle, Germany), Butazolidin (Novartis Pharma, Germany), Butazone (Major, USA), Butrex (Noristan, South Africa), Ticinil (Boehringer Ingelheim, Italy).

Oxyphenbutazone [*129-20-4*], 4-*n*-butyl-1-(4-hydroxyphenyl)-2-phenyl-3,5-pyrazolidinedione, $C_{19}H_{20}N_2O_3$, M_r 324.37, *mp* 124 – 125 °C.

Synthesis: heating 1-(4-benzyloxyphenyl)-2-phenylhydrazine with diethyl-*n*-butylmalonate in the presence of sodium ethoxide at 140 °C followed by acidification gives 1-(4-benzyloxyphenyl)-4-*n*-butyl-2-phenyl-pyrazolidine-3,5-dione, which is unblocked by catalytic reduction (Raney nickel) to yield oxyphenbutazone [46].

Oxyphenbutazone

Oxyphenbutazone is one of the metabolites formed in the liver following administration of phenylbutazone. Given orally it causes fewer gastrointestinal adverse effects than phenylbutazone and is used at 300 – 400 mg/d for the same indications as the parent drug.

Trade names: Diflamil (Belmac, Spain), Phlogont (Azupharma, Germany), Tabazone (Major, USA).

Apazone, azapropazone [*13539-59-8*], 5-(dimethylamino)-9-methyl-2-propyl-1*H*-pyrazolo[1,2*a*][1,2,4]benzotriazine-1,3-(2*H*)-dione, $C_{16}H_{20}N_4O_2$, M_r 300.37, *mp* 228 °C.

Synthesis: a mixture of 1,2-dihydro-3-dimethylamino-7-methylbenzotriazine, diethyl propylmalonate, and sodium ethoxide in xylene is heated over a period of time to 150 °C, cooled, and acidified to give the desired product [47].

Apazone is a complex pyrazolidinedione used at 600 – 1200 mg/d to achieve an anti-inflammatory effect comparable to phenylbutazone. It is tightly bound to plasma protein and may displace anticoagulants and hypoglycemic agents. Its plasma half-life is 8 – 12 h. It is well tolerated with only a low incidence of gastric disturbances. As with all pyrazolone derivatives, the potential for bone marrow suppression exists and careful monitoring of the patient's hematologic state is recommended.

Trade names: Cinnamin (Chemiphar, Japan), Prolixan (Siegfried, Greece), Rheumox (Wyeth, UK), Xani (Farmakos, Yugoslavia).

Apazone

Piroxicam [*36322-90-4*], 4-hydroxy-2-methyl-*N*-2-pyridinyl-2*H*-1,2-benzothiazine-3-carboxamide1,1-dioxide, $C_{15}H_{13}N_3O_4S$, M_r 331.35, *mp* 198 – 200 °C.

Synthesis: an improved procedure using 2-methoxyethyl 2-chloroacetate in place of methyl 2-chloroacetate for the alkylation of sodium saccharin has been described [48]. The resulting 2-methoxyethyl saccharin-2-acetate is treated with sodium 2-methoxyethoxide in dimethyl sulfoxide, then acidified to give 2-methoxyethyl 4-hydroxy-2*H*-1,2-benzothiazine-3-carboxylate 1,1-dioxide, which is *N*-alkylated with methyl iodide in acetone – aqueous sodium hydroxide. The resulting 2-methoxyethyl 4-hydroxy-2-methyl-2*H*-1,2-benzothiazine-3-carboxylate 1,1-dioxide is heated with 2-aminopyridine in xylene to give piroxicam [49].

Piroxicam

Piroxicam, the first of a new class of NSAIDs known as "oxicams," was introduced in 1979 for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, gout, and acute musculoskeletal disorders [48]. This compound was the result of a long and intensive effort to develop a potent NSAID having a novel structure and a plasma half-life sufficiently long to maintain continuous therapeutic blood levels on a once-a-day dosing regimen. Piroxicam is a potent competitive inhibitor of cyclooxygenase and lowers blood levels of prostaglandins in humans. Its ability to inhibit the infiltration of polymorphonuclear leukocytes into inflamed joints has been demonstrated in animals. Its potency and long plasma half-life of 40 h in humans allow for once-a-day dosing at 20 mg. A high incidence of gastric irritation results from this agent.

Trade names: Brexidol (Pharmacia & Upjohn, Germany), Brexin (Pharmacia & Up-

john, Austria), Doblexan (Organon, Spain), Durapirox (Durachemie, Germany), Felden (Mack/Pfizer, Germany), Piro-Phlogont (Azupharma, Germany), Ruvamed (Coup, Greece).

3.6. Anthranilates

Mefenamic acid [*61-68-7*], 2-[(2,3-dimethylphenyl)amino]benzoic acid, $C_{15}H_{15}NO_2$, M_r 241.28, *mp* 230 – 231 °C.

Synthesis: mefenamic acid is prepared via the Jourdan – Ullmann – Goldberg synthesis utilizing either anthranilic acid and 3-bromo-1,2-dimethylbenzene or 2,3-dimethylaniline and an *o*-halobenzoic acid in the presence of a copper catalyst and a proton acceptor [50].

Mefenamic acid has mild anti-inflammatory properties and is used primarily as a short-term analgesic. Gastrointestinal disturbances, including possibly allergic diarrhea and potential renal toxicity, limit its use.

Trade names: Lysalgo (SIT, Italy), Opustan (Opus Pharm, UK), Parkemed (Parke Davis, Germany), Ponstan (Werner-Lambert, Switzerland), Ponstel (Parke Davis, USA), Pontal (Sankyo, Japan).

Flufenamic acid [*530-78-9*], 2-{[3-(trifluoromethyl)phenyl]amino}benzoicacid, $C_{14}H_{10}F_3NO_2$, M_r 281.24, *mp* 125 °C.

Synthesis: refluxing a mixture of 2-iodobenzoic acid and 3-trifluoromethylaniline in aqueous potassium carbonate containing copper-bronze as the catalyst affords, after acidification, the desired flufenamic acid [51].

Flufenamic acid

Flufenamic acid is used at 600 – 800 mg/d to provide a beneficial therapeutic effect in chronic polyarthritis. The adverse effects most often encountered are gastrointestinal disturbances.

Trade names: Ansatin (Ono, Japan), Arlef (Sankyo, Japan), Felunamin (Hokuriko, Japan), Romafen (Biofarma, Turkey).

Meclofenamic Acid [*644-62-2*], 2-[(2,6-dichloro-3-methylphenyl)amino]benzoicacid, $C_{14}H_{11}Cl_2NO_2$, M_r 296.15, *mp* 257 – 259 °C.

Synthesis: heating a mixture of potassium 2-bromobenzoate, 2,6-dichloro-3-methylaniline, morpholine, diglyme (diethylene glycol dimethyl ether), and cupric bromide at 145 – 155 °C and subsequent acidification afford meclofenamic acid [52].

Meclofenamic acid

Meclofenamic acid is available as its sodium salt hydrate. This drug is indicated for the relief of acute and chronic rheumatoid arthritis and osteoarthritis. Gastrointestinal distress, including diarrhea, nausea, vomiting, and abdominal pain, is the most commonly reported adverse effect.

Trade names: Meclodol (Parke Davis, Italy), Meclomen (Parke Davis, Portugal, USA), Stadium (Menarini, Belgium).

Niflumic acid [*4394-00-7*], 2-{[3-(trifluoromethyl)phenyl]amino}-3-pyridinecarboxylic-acid, $C_{13}H_9F_3N_2O_2$, M_r 282.23, *mp* 204 °C.

Synthesis: heating a mixture of 2-chloronicotinic acid, 3-trifluoromethylaniline, and a catalytic amount of potassium iodide at 140 °C affords the desired niflumic acid [53].

Niflumic acid

Niflumic acid has been used effectively to treat rheumatoid arthritis, psoriatic arthritis, and hypertrophic osteoarthritis of the hip and knee. Gastric complications are the chief adverse effects of this drug.

Trade names: Actol (Mayrhofer, Austria; Upsamedica, Spain), Donalgin (Gedeon Richter, Hungary), Livornex (Genepharm, Greece), Niflam (Upsamedica, Italy), Nifluril (UPSA, France; Upsamedica, Belgium, Switzerland, Portugal).

3.7. Nonacidic Drugs

Proquazone [*22760-18-5*], 7-methyl-1-(1-methylethyl)-4-phenyl-2(1*H*)-quinazolinone, $C_{18}H_{18}N_2O$, M_r 278.35, *mp* 137 – 138 °C.

Synthesis: proquazone is prepared by the alkylation of 2-amino-4-methylbenzophenone with 2-iodopropane in the presence of sodium carbonate to give 4-methyl-2-[(1-methylethyl)amino]benzophenone, which is condensed with urethane in the presence of zinc chloride at 190 °C [54].

Proquazone

Proquazone has been used successfully to treat rheumatoid polyarthritis. At 900 mg/d it is comparable in effect to 150 mg/d of indomethacin. Gastrointestinal disturbances are the principal adverse effects observed with its use.

Trade names: Biarison (Swiss-Pharma, Egypt; Biochemie, Austria; ICN Alkaloida, Hungary; Sandoz, Finland, Turkey).

Ditazole [*18471-20-0*], 2,2′-[(4,5-diphenyl-2- oxazolyl)imino]diethanol, $C_{19}H_{20}N_2O_3$, M_r 324.38, *mp* 96 – 98 °C (monohydrate).

Synthesis: ditazole is prepared by heating 2-chloro-4,5-diphenyloxazole and diethanolamine in ethanol [55].

Ditazole is an anti-inflammatory analgesic agent that is of interest primarily for its ability to inhibit platelet aggregation. For example, it normalizes the enhanced platelet activity in cerebrovascular patients suffering transient ischemic attacks.

Trade name: Ageroplas (Lepori, Spain; Serono, Italy), Fendazol (Lepori, Portugal).

Ditazole

3.8. Selective COX-2 Inhibitors

Celecoxib [*169590-42-5*], 4-[5-(4-methylphenyl)-3-(trifluoromethylpyrazol-1-yl]benzenesulfonamide, $C_{17}H_{14}F_3N_3O_2S$, M_r 381.37, *mp* 157 – 159 °C.

Synthesis: Celecoxib is prepared by condensation of 4-methylacetophenone with ethyl trifluoroacetate to give 4,4,4-trifluoro-1-(4-methylphenyl)butane-1,3-dione, which is cyclized with 4-hydrazinophenylsulfonamide [56]:

Celecoxib

Celecoxib (SC-58635) is a selective inhibitor of the COX-2 isozyme. Based on human recombinant enzyme assays celecoxib was shown to be 375-fold more selective for COX-2 (IC_{50} for COX-2: 4×10^{-8} M vs. IC_{50} for COX-1: 1.5×10^{-5} M). Celecoxib displays a plasma half-life of 10 – 12 h. Celecoxib is indicated for relief of the signs and symptoms of osteoarthritis (recommended oral dose is 200 mg per day administered as a single dose or as 100 mg twice per day) and rheumatoid arthritis in adults (recommended oral dose is 100 to 200 mg twice per day). In comparison to traditional NSAIDs, celecoxib causes fewer gastrointestinal side effects. Celecoxib has been associated with adverse effects such as headache, change in bowel habits, abdominal discomfort, and dizziness.

Trade name: Celebrex (G. D. Searle & Co., USA).

Rofecoxib [*162011-90-7*], 4-[4-(methylsulfonyl)phenyl]-3-phenylfuran-2(5*H*)-one, $C_{17}H_{14}O_4S$, M_r 314.36, *mp* 208 °C.

Synthesis: Rofecoxib can be obtained by different synthetic routes [57], e.g., by condensation of phenylacetic acid with ethyl bromoacetate to ethyl 2-phenylacetoxyacetate, which is then cyclized to a hydroxyfuranone. Subsequently, the hydroxyfuranone reacts with trifluoromethanesulfonic (triflic) anhydride to the corresponding triflate which reacts with LiBr to yield a bromofuranone. The bromofuranone is condensed with 4-(methylsulfanyl)phenylboronic acid to give 4-[4-(methylsulfanyl)phenyl]-3-phenylfuran-2(5*H*)-one which is finally oxidized to rofecoxib.

The selective COX-2 inhibitor rofecoxib is a methylsulphonylphenyl derivative. In comparison to celecoxib, rofecoxib is slightly more potent and has a longer half life of ca. 17 h. Based on human recombinant enzyme assays rofecoxib was shown to be > 800-fold more selective for COX-2 (IC_{50} for COX-2: 1.8×10^{-8} M vs. IC_{50} for COX-1: 1.5×10^{-5} M). Rofecoxib is indicated for relief of the signs and symptoms of osteoarthritis (recommended starting dose is 12.5 mg once daily, maximum recommended dose is 25 mg/d), for the management of acute pain in adults and for the treatment of primary dysmenorrhea (recommended initial doses are 50 mg once daily, use of rofecoxib for more than 5 d in management of pain has not been studied). Rofecoxib causes a significantly lower incidence of upper-gastrointestinal adverse effects (perforations, ulcers, and bleeding) than conventional NSAIDs. Most common adverse events associated with rofecoxib are diarrhoea, headache, nausea, and upper respiratory tract infection.

Trade name: Vioxx (Merck & Co., USA).

Rofecoxib

4. Antirheumatic Agents

This class of agents encompasses a wide variety of structural and pharmacologic types, including gold, antimalarials, sulfhydryl compounds, and immunoregulants (both immunosuppressants and immunostimulants). These drugs are characterized in many instances by a slow onset of activity and, in contrast to the anti-inflammatory agents discussed heretofore, do have a beneficial effect on the underlying disease process. The acronyms SAARDs (slow acting antirheumatic drugs) and DMARDs (disease modifying antirheumatic drugs) have been applied to these substances.

4.1. Gold

Until the advent of the orally administered auranofin, gold preparations used in the treatment of rheumatoid arthritis were administered parenterally. Ionic gold in its monovalent state is preferred. Gold(I) has a strong affinity for sulfur relative to other elements and the antirheumatic preparations used contain gold bound to an organosulfur carrier. Indeed, the ability of gold to bind to physiologic sulfhydryl groups is thought to be an important factor in its bioactivity. Nevertheless, the actual mechanism of action remains to be determined.

The following activities of gold related to inflammation have been observed:

1) protection of collagen against collagenase

2) inhibition of lysosomal enzymes
3) prevention of denaturation of macro-globulins and formation of antigen – antibody complexes
4) uncoupling of oxidative phosphorylation
5) inhibition of leukocyte chemotaxis

Chrysotherapy (treatment with gold salts) is successful in approximately 80 % of patients. Profound modification and remission of the disease, including retardation of the abnormal growth of synovial tissue over the joint surface, are observed. Unfortunately, a high incidence of adverse effects (25 – 50 %) counterbalances the beneficial effects. Cutaneous hypersensitivity and lesions of mucous membranes are most common. Blood disorders including thrombocytopenia, leukopenia, agranulocytosis, and aplastic anemia occur. Renal effects, as evidenced by proteinuria, are observed.

Aurothioglucose [*12192-57-3*], (1-thio-D-glucopyranosato)gold, $C_6H_{11}AuO_5S$, M_r 392.22.

Synthesis: gold thioglucose is prepared by adding a solution of gold bromide to an aqueous solution of thioglucose that contains sulfur dioxide. After heating, the product is precipitated by the addition of ethanol [58].

Aurothioglucose

Aurothioglucose is an antirheumatic used to treat active progressing rheumatoid arthritis and nondisseminated lupus erythematosus. The drug is administered at weekly intervals by intramuscular injection (10 mg, 25 mg, then 50 mg) until 800 mg to 1 g has been given. If improvement takes place, the drug is then administered at levels that balance the urinary excretion of gold. During this maintenance therapy the interval between injections is lengthened to 3 – 4 weeks.

Trade names: Aureotan (BYK Gulden, Germany), Solganal (Schering, USA, Yugoslavia).

Sodium aurothiomalate [*12244-57-4*], mercaptobutanedioic acid monogold(I) sodiumsalt, $C_4H_4AuNaO_4S/C_4H_3AuNa_2O_4S$.

Synthesis: a solution of thiomalic acid and 3 equivalents of sodium hydroxide are mixed with an aqueous suspension of gold(I) iodide. The product, a mixture of the mono- and disodium salts, is precipitated by the addition of ethanol [59].

Sodium aurothiomalate

Sodium aurothiomalate is administered in the same manner and for the same indications as aurothioglucose.

Trade names: Aurolate (Pasadena, USA), Myocrisin (Rhône-Poulenc Rorer, Denmark, Sweden, Finland), Tauredon (BYK Gulden, Germany).

Auranofin [*34031-32-8*], (2,3,4,6-tetra-*O*-acetyl-1-thio-β-D-glucopyranosato-*S*)(triethylphosphine)gold, $C_{20}H_{34}AuO_9PS$, M_r 678.49, *mp* 110 – 111 °C.

Synthesis: ethanolic thiodiglycol is treated first with aqueous gold(I) acid chloride trihydrate, then with ethanolic triethylphosphine to give triethylphosphine gold(I) chloride, which is added to an aqueous solution of *S*-(2,3,4,6-tetra-*O*-acetylglucopyranosyl)pseudothiourea hydrobromide and potassium carbonate to give the desired auranofin [60].

Auranofin was the first orally active gold preparation available for treatment of rheumatoid arthritis. Although it is incompletely absorbed, administration of 3 mg twice a day has resulted in profound improvement in patients, approaching the efficacy of parenteral gold, after a period of 8 – 12 weeks. The principal adverse effects with auranofin are diarrhea and loose stools. Mucocutaneous effects, such as rash and pruritis, also were seen, as were abnormalities in taste; but in general, it seems less toxic than parenteral gold.

Trade names: Aktil (Lek, Yugoslavia), Ridaura (Smith Kline Beecham, USA), Ridauran (Robapharm, France).

Auranofin

4.2. Antimalarials

Several antimalarial agents – chloroquine, hydroxychloroquine, and dapsone – possess clinically useful anti-inflammatory properties. Hydroxychloroquine is preferred over chloroquine for the treatment of rheumatoid, but not other types of arthritis. When used clinically at a low dose of 4 – 6 mg/kg, safety, moderate effectiveness, and a low patient dropout rate can be achieved. Retinopathy can be minimized by careful ophthalmologic monitoring. The clinical effect is delayed and good-to-moderate suppression of the disease is observed after 6 – 9 months of therapy. Hydroxychloroquine also is effective in treating systemic lupus erythematosus.

Dapsone is clinically effective in treating rheumatoid arthritis. Decreases in both erythrocyte sedimentation rate and plasma levels of *C*-reactive protein have been observed. Unfortunately, its propensity to induce blood disorders and its carcinogenic potential preclude its widespread use.

The mechanism of the antirheumatic action of antimalarials is still under investigation. Inhibition of various cellular functions of lymphocytes and macrophages has been observed.

For structure, properties, and preparation → Chemotherapeutics.

4.3. Sulfhydryl Compounds

d-Penicillamine [*52-67-5*], 3-mercapto-D-valine, $C_5H_{11}NO_2S$, M_r 149.21, *mp* 198.5 °C.

Synthesis: D-penicillamine can be synthesized in a multistep process that begins with heating isobutyraldehyde, pyridine, sulfur, and ammonia in benzene to form 5,5-dimethyl-2-isopropyl-Δ^3-thiazoline. Treatment with hydrogen cyanide gives 4-cyano-5,5-dimethyl-2-isopropylthiazolidine, which on acid hydrolysis gives D,L-penicillamine hydrochloride [61]. Resolution is accomplished by conversion of the racemate to D,L-3-formyl-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid by treatment first with acetone, then with acetic formic anhydride. The enantiomers are separated in the usual manner, using, for example, L-lysine [62] or D-(−)-threo-1-(4-nitrophenyl)-2-aminopropane-1,3-diol [63]. Acidification liberates D-3-formyl-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid, which is hydrolyzed with hydrochloric acid to yield D-penicillamine hydrochloride. Neutralization with ethanolic triethylamine affords D-penicillamine.

Improvements have also been made in the preparation of D-penicillamine from penicillins by conversion to the penicilloic acid, which when treated with concentrated hydrochloric acid and methanolic mercuric chloride gives D,L-penicillamine as its mercuric thiolate. Treatment with hydrogen sulfide in hydrochloric acid gives D,L-penicillamine hydrochloride [64], which is resolved as described previously.

D-Penicillamine is as effective as gold in bringing about remission in severe rheumatoid arthritis. As with gold it is administered in gradually increasing amounts over a long period of time (4 – 6 months) before beneficial effects are seen. Its mechanism of action is unknown. Speculations concerning the basis for its effectiveness include: copper chelation and mobilization as well as effects on collagen biosynthesis, lymphocyte and monocyte function, antibody response, and cellular immunity. The profound therapeutic benefits of D-penicillamine are offset by a high incidence of adverse reactions. Skin rashes similar to those seen during chrysotherapy constitute the most common adverse effect. Dyspepsia and hypogusia also are encountered. The most serious problem is bone marrow suppression, evidenced by thrombocytopenia and agranulocytosis. Renal toxicity with resultant albuminuria also is observed frequently.

Trade names: Artamin (Sanabo, Austria), Atamir (Sandoz, Denmark), Dimetylcystein (Lilly, Denmark), Metalcaptase (Knoll, South Africa), Reumacillin (Leiras, Finland), Trisorcin (Merckle, Germany), Trolovol (Asta Medica, Germany).

Pyritinol, pyrithioxin [*1098-97-1*], 3,3′-(dithiodimethylene)bis(5-hydroxy-6-methyl-4-pyridinemethanol), $C_{16}H_{20}N_2O_4S_2$, M_r 368.48, *mp* 218 – 220 °C.

Synthesis: treatment of pyridoxine with hydrobromic acid gives 4,5-bis(bromomethyl)-3-hydroxy-2-methylpyridinium bromide, which when treated in the cold with potassium ethyl xanthate gives ethyl 4-hydroxymethyl-3-hydroxy-2-methyl-3-pyridyl methylxanthate. Hydrolysis and oxidation are carried out in aqueous-alcoholic ammonia to give the disulfide pyritinol [65].

Pyritinol, the disulfide of pyridoxine-5-thiol, is marketed as a cerebral stimulant in Europe. Both the thiol and the disulfide have been shown to have D-penicillamine-like activity in the treatment of rheumatoid arthritis. Adverse effects are similar to those seen with D-penicillamine. Occasionally, pyritinol seems effective and better tolerated in some individuals who fail to respond to D-penicillamine.

Trade names: Ansefal (Anka, Turkey), Bonifen (Merck, Portugal), Enbol (Chugai, Japan), Encefabol (Merck, Brazil, Greece, Czech Republic), Encephabol (Merck, Austria, CIS, South Africa), Neuroxin (Yamanouchi, Japan).

4.4. Immunoregulants

The idea that autoimmune mechanisms might be involved in the pathogenesis of rheumatoid arthritis led to the use of immunosuppressive therapy as far back as the 1950s. More recently, its use in severe forms of the disease has been studied carefully.

The folic acid analogue *methotrexate* is a very promising drug for the treatment of rheumatoid arthritis. At doses used for the treatment of rheumatic diseases its principal mode of action probably relates to an inhibition of aminoimidazolecarboxamide ribonucleotide transformylase and thymidylate synthase, plus enhanced adenosine release.

The alkylating agent *cyclophosphamide* is sometimes used in rheumatoid arthritis. A more frequent use is precluded by its considerable toxicity. Cyclophosphamide nonspecifically kills cells by reacting with DNA and RNA molecules.

The immunosuppressive drug *azathioprine* is FDA-approved for treatment of rheumatoid arthritis. Azathioprine is believed to interfere with cell division by inhibiting metabolism and synthesis of proteins and DNA.

Novel therapeutic approaches for treatment of autoimmune rheumatic diseases include The immunosuppressive drug *cyclosporin A* and *leflunomide*. Cyclosporine A is an immunosuppressive drug used to prevent organ rejection which has been shown to provide benefit in rheumatoid arthritis. Most common adverse effects of this drug are renal damage, hypertension, and increased body hair. Leflunomide is an isoxazol derivative that has no struc-

tural relationship to other known immunoregulatory drugs [66], [67]. In vivo leflunomide is rapidly metabolized to its active form, a malononitrilamine termed A771726. The substance may serve as an immunomodulatory agent in rheumatoid arthritis by preferentially causing cell arrest of autoimmune lymphocytes through inhibition of the enzyme dihydroorotate dehydrogenase, which catalyzes a critical step in the production of uridine monophosphate (rUMP). A decrease in rUMP leads to cell cycle arrest in lymphocytes. Furthermore, leflunomide inhibits tyrosine kinase activation in T cells after stimulation of the IL-2 receptor. Tyrosine kinase inhibition has been proposed to partially explain the immunosuppressive action of leflumide.

5. Inhibitors of Tumor Necrosis Factor

Clinical trials suggest that *monoclonal antibodies* directed against TNF provide a novel approach for the treatment of rheumatoid arthritis [68], [69]. The proinflammatory cytokine TNF has been implicated in the pathogenesis of rheumatoid arthritis. TNF concentrations are increased in the synovial fluid of persons with active rheumatoid arthritis, and increased TNF plasma levels have been shown to be associated with joint pain. TNF increases synoviocyte proliferation, and triggers the release of secondary mediators involved in the recruitment of inflammatory cells during neoangiogenesis and in the process of joint destruction. Infliximab is a chimeric TNF monoclonal antibody (CA2) which was the first monoclonal antibody to be investigated for the treatment of rheumatoid arthritis. Etanercept is a recombinant version of the soluble p75 TNF receptor linked to the Fc portion of human immunoglobulin G1. Etanercept competitively inhibits the binding of TNF to its cell surface receptors, thereby inhibiting the biological activity of TNF in a reversible manner.

6. Natural Products

Colchicine [*477-27-0*], (*S*)-*N*-(5, 6, 7, 9-tetrahydro-1, 2, 3, 10-tetramethoxy-9-oxobenzo[*a*]heptalen-7-yl)acetamide, $C_{22}H_{25}NO_6$, M_r 399.43, *mp* 142 – 150 °C.

Production: colchicine is obtained by extracting the seeds and/or corm of *Colchicum autumnale* Linné [70].

Colchicine

Colchicine is a specific drug for the treatment of gouty arthritis. It is especially useful in acute attacks but also is used prophylactically in conjunction with other drugs, such as allopurinol or phenylbutazone. The drug is believed to act by disrupting microtubular assembly in inflammatory cells, thereby impairing both their locomotion and their membrane function, including phagocytosis and the release of inflammatory mediators. The alkaloid is extremely toxic and must be used with care. Gastrointestinal adverse effects include nausea, vomiting, and diarrhea. Blood disorders, including agranulocytosis and aplastic anemia, sometimes are seen after prolonged administration of this drug.

Trade names: Colchicina (Smith Kline, Brazil), Colchicine (Various, USA), Colchicum-Dispert (Solvay, Poland), Colabid (Major, USA).

Orgotein [*9016-01-7*], M_r 34000, is the name applied to a group of metalloproteins obtained from various tissuesources, such as hemolyzed plasma-free bovine erythrocytes [71] or beef liver [72]. They are copper – zinc/protein chelates with molecular masses of about 34 000. These compounds have potent superoxide dismutase activity. When administered directly into the joint at 4 mg/week for 6 weeks, marked improvement in the mobility of acute rheumatoid patients occurred. Synovial fluid levels of rheumatoid factor and prostaglandin E_2 were reduced.

Trade names: Ontosein (Tedec-Meiji, Spain), Peroxinorm (Grünenthal, Austria), Serosod (Serono, Italy).

The article describes the properties, production, and usage of the element antimony and its primary compounds. Stibnite, which is referred to as crude antimony when its Sb_2S_3 content is above 90 %, has a low melting point and it can be extracted by melting (liquidation). Antimony metal is recovered from ore primarily by pyrometallurgical techniques. Because rich ores are becoming rare, greater recourse is being taken to intermediates in processing and metal industries. Hydrometallurgical processing is suitable for some ores containing precious metals and is used by the Sunshine Mining Co. (USA). Refining and fine purification techniques are used for production of pure antimony metal.There is growing demand for extremely pure antimony. Antimony oxide is being used as flame retardant in increasing quantities. Antimony is a component of many lead and tin alloys, which are important materials for making bearings and solders. Preparation, properties, and usage of the antimony halides, oxides, sulfides, and other compounds, as well as organometallic compounds are described.Other important aspects are recycling, economics, and toxicology.

1. Introduction [14, 15]

Antimony [*7440-36-0*], Sb, is an element of group 15 having atomic number 51 and atomic mass M_r 121.75. Two isotopes occur in nature, mass numbers 121 [*14265-72-6*] and 123 [*14119-16-5*]. The configuration in the outer electron shell is $5\,s^2 5\,p^3$. If these electrons are

10.1002/14356007.a03_055.pub2

donated, antimony is electropositive and trivalent, as in $SbCl_3$, or pentavalent, as in $SbCl_5$; if three electrons are added to the outer shell, the antimony is electronegative and trivalent, as in Li_3Sb.

Usually antimony is a white lustrous metal of average hardness, 3.0 on the Mohs scale. It is brittle and easy to pulverize. If it solidifies slowly, pure antimony has a foliated structure; if rapidly, a granular structure. It forms rhombohedral crystals.

Metallic antimony is the only stable allotrope. There are unstable forms: yellow antimony, black amorphous antimony, and what is known as explosive antimony. Yellow antimony is formed when air or oxygen is passed through liquid stibine. Black amorphous antimony is obtained by rapidly cooling antimony vapors and is also formed from yellow antimony at − 90 °C. At room temperature black antimony slowly reverts to metallic antimony, and at 400 °C reversion is spontaneous. Black amorphous antimony ignites spontaneously in air. Explosive antimony is obtained by electrolysis of antimony(III) chloride solution in hydrochloric acid at a high current density with an antimony anode and a platinum cathode. It consists of black amorphous antimony contaminated with antimony trichloride.

History [14, 16]. Antimony was known to the Chinese 5000 years ago. The ancient Egyptians were also acquainted with it, but they considered it to be a variety of lead, a belief that persisted until the 16th century. The first instructions on processing the Latin *stibium* or the Egyptian *stim* (antimony glance or stibnite) appeared at the beginning of our era. Pedanios Dioskurides and Pliny the Elder referred to antimony glance as platyophthalmon (eye dilator), calliblephary (eyelid cosmetic), and gynaikeios (feminine), because antimony(III) sulfide powder was then an ophthalmic ointment and a coveted cosmetic.

The word *Antimonium* seems to have been first used for antimony(III) sulfide in 1050 by Constantinus Africanus. Light was gradually shed on the chemistry of antimony and on antimony therapy by Paracelsus (1526 – 1541), Andreas Libavius (*Alchemia*, 1597, and the *Syntagmatis Arcanorum* volumes, 1613 – 1615), the Benedictine monk Basilius Valentinus (*Triumphwagen Antimonii*, 1604), N. Lemery (*Traité de l'Antimoine*, 1707), and other works of the iatrochemical epoch. At an early stage, alchemists understood the significance of antimony for separating gold from silver. The recovery of *antimonium crudum* from its ores was described in detail by Lazarus Ercker (1574) and Georgius Agricola (*De re metallica*, 1556).

2. Physical Properties [14, 16, 17]

Density	
solid at 20 °C	6.688 g/cm^3
liquid at 630.5 °C	6.55 g/cm^3
Melting point	630.5 °C
Heat of fusion	10.49 kJ/mol
Boiling point at 101.3 kPa	1325 °C
Tensile strength	10.8 N/mm^2
Modulus of elasticity	566 N/mm^2
Surface tension	
solid at 432 °C	317.2 mN/m
liquid at 630 °C	349 mN/m
liquid at 1200 °C	255 mN/m

The surface tension of the solid decreases nearly linearly with temperature. The slope at the melting point is − 0.07 mN m^{-1} K^{-1}.

Molar heat capacity at 630.5 °C	
solid	30.446 J mol^{-1} K^{-1}
liquid	31.401 J mol^{-1} K^{-1}
Coefficient of linear expansion between	
0 and 100 °C	10.8×10^{-6} °C^{-1}
Thermal conductivity at 0 °C	18.51 W m^{-1} K^{-1}
at 100 °C	16.58 W m^{-1} K^{-1}

Roughly 1/20th of the thermal conductivity of copper. The thermal conductivity of antimony depends on the grain size and the direction in the crystal.

Electrical resistivity at 0 °C	30.0×10^{-6} Ω cm
Molar susceptibility at 20 °C	-99.0×10^{-6}

Polycrystalline antimony is diamagnetic.

3. Chemical Properties [14, 16, 17]

Pure antimony does not change in air at room temperature, and it is not tarnished in humid air or pure water. If antimony is heated to redness in air, the molten metal ignites. Above 750 °C, steam oxidizes liquid antimony to antimony trioxide, and hydrogen is evolved. Antimony can be removed from lead – antimony alloys with steam. Antimony cannot be ignited in a current

of hydrogen. If it is heated to redness in a current of nitrogen, gray vapors are given off, which condense to amorphous antimony.

Neither solid nor liquid antimony dissolves nitrogen. Fluorine, chlorine, bromine, and iodine react violently with antimony, even at room temperature, to form trihalides. The reaction with chlorine yields either $SbCl_3$ or a mixture of $SbCl_3$ and $SbCl_5$. Antimony(III) sulfide is the product of the reaction with sulfur, hydrogen sulfide, or dry sulfur dioxide. In the presence of an oxidizing agent or sulfur, aqueous sodium sulfide dissolves antimony to yield sodium thioantimonite. Yellow ammonium sulfide and sulfur-containing potassium sulfide solutions also readily dissolve antimony.

Molten antimony reacts with phosphorus, arsenic, selenium, and tellurium but not with boron, carbon, and silicon. The eutectic with lead contains 13 wt % antimony and melts at 246 °C.

Antimony is resistant to concentrated hydrofluoric, dilute hydrochloric, and dilute nitric acids. It is readily soluble in a mixture of nitric and tartaric acids and in aqua regia. Phosphoric acid and a few organic acids also dissolve the metal, although acetic acid hardly belongs to this category. At room temperature it is not attacked by dilute or concentrated sulfuric acid. It is attacked at 90 – 95 °C by concentrated sulfuric acid, and sulfur dioxide is evolved.

Pure antimony is resistant to solutions of ammonium and alkali-metal hydroxides and to molten sodium carbonate. If heated to redness, it reacts with molten sodium or potassium hydroxide to form hydrogen gas and antimonites.

In the electrochemical series antimony falls between hydrogen and bismuth: H, Sb, Bi, As, Cu.

4. Occurrence

The average antimony content of the earth's crust has been estimated at $(2 - 5) \times 10^{-5}$ %. Most antimony lodes occur in areas of volcanic activity and frequently in volcanic rocks themselves. They are found predominantly in ancient formations ranging up to the Carboniferous. Antimony deposits are seldom of sedimentary or epigenetic origin.

The most important antimony ore is rhombic *antimony glance* (gray antimony, antimonite, or stibnite), Sb_2S_3. It contains 71.7 % antimony and occurs as characteristic black acicular crystals. Other ores include antimony oxides (valentinite, Sb_2O_3, rhombohedral; senarmontite, Sb_2O_3, cubic; cervantite, Sb_2O_4, orthorhombic), antimony hydroxides (stibiconite, $Sb_2O_4 \cdot H_2O$), antimony oxide sulfides (kermesite, pyrostibite, red antimony, 2 $Sb_2S_3 \cdot Sb_2O_3$), native antimony, and double sulfides (jamesonite, $Sb_2S_3 \cdot 2$ PbS, which may contain silver; tetrahedrite, $Sb_2S_3 \cdot 4$ Cu_2S_2; and livingstonite, 2 $Sb_2S_3 \cdot HgS$). More than 100 minerals containing antimony are known: there are eight antimonides, one sulfide (stibnite), 59 mixed antimonides and sulfides, and 46 oxide minerals [14, 18].

Simple antimony deposits consist mainly of stibnite or, rarely, native antimony in a siliceous gangue, commonly with some pyrite, and in places a little gold and small amounts of other metal sulfides, principally those of silver and mercury. Most of these geologically simple stibnite deposits do not individually contain more than several thousand tonnes of ore. Deposits of this type are found in the world's most productive antimony districts, including those of Bolivia, China, Mexico, and the Republic of South Africa [18, 19].

Complex antimony deposits consist of stibnite associated with pyrite, arsenopyrite, cinnabar, or scheelite, or of antimony sulfo salts with varying amounts of copper, lead, and silver, as well as common sulfides of these metals and zinc. Ores of the complex deposits are mined primarily for gold, lead, silver, tungsten, or zinc; antimony is recovered as byproduct. The tetrahedrite ores found in the Coer d'Alene district of Idaho are a typical example of a complex silver – copper ore which is mined primarily for its silver and copper content and from which antimony is recovered in a concentrate as a byproduct [18, 20].

Principal identified world antimony resources are estimated to be about $(3 - 5) \times 10^6$ t Sb. About 50 % of total world resources are located in China, mainly in Hunan province in the south. Further major antimony resources of about 200 000 to 300 000 t Sb content are located in Bolivia, South Africa, Mexico, and the former Soviet Union (Central Asia, the Ural

and Caucasus mountains). Deposits of about 100 000 t are located in Australia, Italy, former Yugoslavia, Malaysia, Thailand, Turkey, and the United States, while small deposits are found in Burma, France, Canada, Morocco, Austria, Peru, Spain, and Zimbabwe [18, 21].

Table 1 lists world mine production of antimony. Total mine production increased from 1993 (86 445 t) to 2001 (15 7000 t) and decreased again until 2003 (81 600 t).

Since 1987 China has been the dominant producer of antimony ores and concentrates. Its strong market position with a share of about 60 – 70 % of world mine production has remained almost constant. Other countries with major productions of primary antimony raw materials are Bolivia (7.1 %), the countries of the former Soviet Union (6.8 %) and South Africa (4.1 %).

The largest antimony mine in the world is the Murchinson Range, which lies in the Lowveld of the north-eastern Transvaal. Many types of minerals are present in the Murchinson belt, including antimony, gold, mercury, copper, zinc, tungsten, titaniferous magnetite, and emeralds. Only three of these commodities — antimony (with gold as a byproduct), gold (ex dumps), and emeralds — are currently exploited. The antimony deposit consists predominantly of stibnite (Sb_2S_3), which is mined down to 60 m underground [19].

In contrast to the large-scale mining in South Africa, most mines in Bolivia are far smaller, the largest being Chilcobija (850 000 t), Caracota (120 000 t) owned by Empressa Unificada SA (EMUSA), and San Luis (35 000 t). In Bolivia antimony ore is also mined down to 50 m below ground [25]. Other small antimony deposits which are mined economically are found in Turkey, where the 400 t Sb mine production is divided between many small ore bodies [26].

Other sources of antimony besides ores are intermediates in the processing of lead and copper ores: flue dusts, speiss, slags from lead refining processes, anode slimes and the electrolyte from the electrolytic copper refineries (Chapter 6.5). Used car batteries are another valuable resource for the recovery of antimony (Chapter 14).

5. Beneficiation

The beneficiation process used depends chiefly on the content of antimony and other substances in the ore. Another important factor is how the ores are dispersed in the rock. If an antimony ore is not closely interlaced with the gangue, hand-picking techniques or jigs suffice for separation [14].

If stibnite (Sb_2S_3) ore contains more than 90 % stibnite, it can be sold directly as Sb_2S_3 (crude antimony). At some mines in Bolivia and in the Republic of South Africa the high-grade sulfide ore is treated by hand-cobbing and sold as lump sulfide ore with 60 % Sb content. Stibnite has a low melting point and it can be extracted by melting if the ore contains 45 – 60 % antimony and is free from lead and arsenic. This technique is called liquidation. If the antimony content lies between 5 and 25 %, the antimony is concentrated in a flue dust by volatilizing roasting (see Chapter 6.1). Antimony ores may contain auriferous antimony sulfides and arsenopyrites. Beneficiating such ores may become profitable again because of their precious metal content [14, 20].

As a rule, low-grade and complex ores or ores in which the minerals are finely dispersed throughout the gangue are beneficiated by flotation, particularly if they contain precious metals [27–30].

Flotation. Figure 1 shows the flow sheet for the recovery of antimony and gold at Murchinson Consolidated in the Republic of South Africa. An integral part of this process are the different flotation operations, which produce a stibnite – gold concentrate as an intermediate product. Different flotation techniques have been in use at Consolidated Murchinson since its formation in 1934, each change in the process being due to variations in the grade of the mined ore and the minor elements accompanying antimony and gold.

Today the ore received by road from the operational shafts has a maximum particle size of approximately 0.4 m and a typical analysis of 1.8 % Sb, 0.2 % As, and 2 g/t Au. In the preliminary comminution circuit the final grind achieved is about 65 – 75 % passing 75 µm. The flotation circuit comprises four parallel rougher banks, four parallel scavenger banks, two cleaner banks, and a recleaner bank. The concentrate produced contains 58.0 % Sb, 25 –

Table 1. World mine production by country (in t Sb content) [20, 22–24]

* Mine production in China varies from 60 000 to 120 000 t/a depending on the literature source.
** France, Austria, Italy, Spain, Czech Republic, Slovakia, Romania, former Yugoslavia, Romania.

Figure 1. Schematic of Consolidated Murchinson's processes for the recovery of gold and antimony [19]

40 g/t Au, 0.17 % As, 0.18 % Pb, 0.11 % Ni, 0.17 % Cu, 1.9 % Fe, 22.3 % S, 9.9 % insoluble matter, 3.0 ppm Se, and 10 ppm Hg. The recovery of antimony of this grade varies between 80 and 88 % depending on the head grade and the type of mineralization. The stibnite – gold concentrate is leached by pressure cyanidation in a pipe reactor to separate the gold from the antimony. Crude and refined antimony oxide is recovered from the final antimony concentrate [19].

In the flotation circuit lead nitrate is used as an activator for antimony flotation, with sodium isobutyl xanthate as a primary collector. Aero promoter 208, a dithiophosphate, acts as a secondary collector for antimony and a promoter for gold flotation. The dithiophosphate has an alcohol base and doubles as a frother, although small amounts of other alcohol-based frothers are used occasionally. Dextrin is used as a gangue depressant. The ore is naturally alkaline owing to the presence of dolomite as a major gangue constituent. Sulfuric acid is therefore used to control the pH: 6.8 – 7.0 in the roughers, 6.5 – 6.8 in the scavengers, and 6 – 6.5 in the cleaners. Additionally, sodium cyanide is used to depress the flotation of arsenic minerals [19, 31].

Liquation. Ores with more than 40 – 60 % Sb_2S_3 and free from lead and arsenic often are beneficiated by heating. Because stibnite, Sb_2S_3, has an unusually low melting point, 546 – 548 °C, it can be separated from the gangue by melting (liquation). Stibnite more than 90 % pure is obtained and is referred to as *crude antimony*. It can be sold as such for producing antimony compounds, or it can be converted to antimony metal.

The commercial product should have a striated crystalline structure and a metallic gloss, and its color should be that of graphite. These properties are attained only if the molten antimony(III) sulfide is cooled very slowly. Ores with less than 40 – 45 % Sb_2S_3 are unsuitable for liquation because the large amount of gangue interferes and too much antimony is retained in the residue.

The ore is best fed in the form of walnut-sized lumps (1 – 4 cm). If the ore is too fine, the molten Sb_2S_3 does not flow. The most suitable temperature range is 550 – 660 °C because the volatilization of the Sb_2S_3 (*bp* 1000 °C) is prevented, and liquation is successful. Liquation is carried out in a reducing atmosphere in crucibles or in reverberatory furnaces. The main impurities in crude antimony are arsenic, lead, and iron sulfide.

6. Recovery of the Metal

Antimony metal is recovered from ore primarily by pyrometallurgical techniques. Either antimony(III) sulfide is converted into the oxide, which is then reduced, or the ore is partially roasted and allowed to react with sulfide to form the metal and sulfur dioxide.

Sulfide ores with antimony contents between 5 and 25 % are roasted to give volatile Sb_2O_3, which is reduced directly to the metal. In many smelters mixed oxide – sulfide ores are processed in water-jacketed furnaces together with recycled material and byproducts containing antimony. Reverberatory furnaces are used mostly for reducing rich oxide materials. The most suitable processes are listed in Table 2 for the various oxide and sulfide ores.

Table 2. Suitable processes for various antimony ores or concentrates

Nature of the ore	Antimony content, %	Process
Sulfide	< 20	volatilizing roasting
Sulfide	< 35	smelting in shaft furnaces
Sulfide	> 60	liquation and cyclone volatilizing
Oxide	< 30	smelting in reverberatory furnaces and shaft furnaces
Oxide	< 50	direct reduction
Mixed sulfide and oxide	–	smelting in shaft furnaces

Special processes are used if the ore is rich in precious metals. Hydrometallurgical techniques can be used to minimize losses of precious metals. For example, crude metal is obtained at the cathode in a hydrometallurgical process used by the Sunshine Mining Co. (Cœur d'Alène district of Idaho, USA). Because rich ores are becoming rare, greater recourse is being taken to intermediates in processing and metal industries. Also, more and more complex ores are being processed.

6.1. Roasting

The sulfide can be oxidized to antimony(III) oxide (volatilizing roasting) or to antimony(IV) oxide (nonvolatilizing or dead roasting). Furnace control in the production of the nonvolatile antimony(IV) oxide is comparatively simple, but the oxide is not separated from the residue. If the ore contains a high proportion of gangue, difficulties are encountered in reduction. As a result this process is used rarely today.

Volatilizing roasting has the advantage that volatile Sb_2O_3 is produced selectively in a 98 % yield and is separated from the residue, which contains the precious metals in a recoverable form. However, temperature and draft control in the furnace is difficult. The oxide forms between 290 and 340 °C in an oxidizing atmosphere, and the rate of reaction attains its maximum at 500 °C, where antimony(IV) oxide begins to form. The basic reaction is

$$2\,Sb_2S_3 + 9\,O_2 \rightarrow 2\,Sb_2O_3 + 6\,SO_2$$

If too much oxygen is available, antimony(IV) oxide is formed:

$$Sb_2S_3 + 5\,O_2 \rightarrow Sb_2O_4 + 3\,SO_2$$

Above 560 °C the rate of reaction drops considerably. During roasting, antimony(IV) oxide can react with antimony(III) sulfide to give antimony(III) oxide:

$$Sb_2S_3 + 9\,Sb_2O_4 \rightarrow 10\,Sb_2O_3 + 3\,SO_2$$

Therefore, the process must be engineered so that Sb_2O_3 is formed rapidly and preferentially. The temperature must be high enough to ensure adequate volatilization, and the oxygen supply must be kept low to inhibit the formation of antimony(IV) oxide. However, if the temperature is too high, part of the charge will melt, envelope the sulfide grains, and prevent their oxidation. During condensation of antimony(III) oxide, the oxygen content in the gas phase must be kept low enough to prevent oxidation of antimony(IV) oxide.

The temperature level is governed by the sulfide content of the ore. Low-grade ores can be roasted between 850 and 1000 °C. If rich ores are roasted, the upper limit is the melting point of the sulfide (546 °C). In practice, the temperature should not exceed 400 °C. The oxygen supply is controlled by mixing wood charcoal or coke breeze with the charge and by admitting only the amount of air required to form carbon monoxide and antimony(III) oxide. The carbon monoxide suppresses oxidation to antimony(IV) oxide. Despite everything, however, formation of antimony(IV) oxide cannot be entirely suppressed. Antimony(IV) oxide, lead(II) oxide, and flue dust are obtained in the first condenser. The antimony(III) oxide condenses in the second, and the very volatile arsenic(III) oxide condenses in the last. If the oxygen concentration in the roaster is too low, partial oxidation can occur and give a mixture of oxide and sulfide melting at 485 °C. If the concentration of oxygen is too high, arsenates and antimonates of lead, copper, and other metals can form and pass into the slag.

A grain size of 5 – 10 cm suffices in conventional processes because fresh surface is always exposed for reaction owing to volatilization of the trioxide. Very low grade ores must be ground more finely to separate the sulfide from the gangue. The yield depends on the process and the sulfide content of the ore, varying between 60 and 90 % or more.

Commercial antimony(III) oxide should be at least 99.5 % Sb_2O_3. If it is finely crystalline, adheres firmly to the fingers, and does not cake, it is considered of good quality. The oxide must be white; a reddish tinge indicates the presence of antimony(III) sulfide. The yellowish shade of selenium and lead(II) oxide is also undesirable. The arsenic content should be on the order of 0.1 %. Typical specifications and grain size distribution [32] are listed below.

Assay	99.5 %
Sb_2O_4	0.209 %
As_2O_3	0.11 %
PbO	0.15 %
Fe_2O_3	0.03 %
SnO	0.001 %
S	0.18 %
Solubility in tartaric acid	> 99.5 %
Solubility in water	< 0.4 %
Whiteness measured by reflectometry	> 90 %
Size distribution	
0 – 1.5 µm	60 %
1.5 – 3 µm	38 %
> 3 µm	2 %
> 44 µm	0.1 %
Apparent density	0.8 kg/L

Commercial refined antimony(III) oxide can be produced by a second roasting process in which the crude oxide is roasted again under controlled conditions. Especially the separation of arsenic and antimony can be an important factor for the production of high-quality antimony oxide. Whilst arsenic oxide has little value, there is a market for antimony oxide [19, 33–37].

Before *mercury-containing antimony ores* are processed, they generally must be roasted below 400 °C to volatilize the mercury. The temperature must be controlled accurately by regulating the admission of air to avoid overheating the charge and thus volatilizing antimony compounds. The roasted ore still contains antimony sulfide. The ore is removed from the furnace and cooled slowly under exclusion of air in special bunkers. The antimony is recovered by reduction or iron precipitation in open-hearth furnaces [38–40].

The *roasting furnaces* most commonly encountered today are rotary kilns. If the throughput is high, antimony(III) oxide yields of 95 – 98 % are attainable. The yield does not depend on the nature of the ore. The antimony content of sulfide ores does not affect the kiln's efficiency; therefore, sorting and flotation of low-grade sulfide ores are unnecessary. Rotary kilns are also suitable for oxide – sulfide ores, reducing the antimony initially to the metal. The metal volatilizes and is oxidized to antimony(III) oxide that is free of nonvolatile impurities and the off-gases produced on reduction. Some rotary kilns are heated not by burners but by hot air blown into them. The gas flow rate is significantly less than that in the old burner-heated furnaces, and less gangue is entrained in the gas stream. Nevertheless, hot-air heating does not entirely avoid temperature peaks, with melting of the charge.

Crude antimony oxide (81 % Sb, 0.3 % As, 0.15 % Ni) is produced by Consolidated Murchinson in the Republic of South Africa by a volatilizing roast of the sulfide concentrate in a rotary kiln. Temperatures in the kiln are in the range 1100 – 1200 °C so that the oxidation of Sb_2S_3 to Sb_2S_3 occurs partly in the gas phase. The conversion of stibnite to the oxide is carried out by the Chemetron Process, which has unique features embodied in the oxidation and cooling control. While the antimony oxide is removed from the kiln continuously, the nonvolatile elements remain in the kiln and are removed in weekly deslagging campaigns. Kiln-feed rates, burner positioning, and cooling rates are important process control parameters that affect product grade and recovery. Refined antimony trioxide of 99.5 % purity is produced by refuming of the crude oxide under rigidly controlled conditions [19, 37].

Cyclone smelting entirely eliminates melting of the charge. The antimony smelter at Vinto, Bolivia, was the first in the Western Hemisphere to use the cyclone furnace smelting process. Conventional antimony roasting consumes large amounts of coal, and the lack of domestic coal has favored the cyclone furnace. The feed contains at least 60 % antimony and less than 0.5 % lead plus arsenic. Antimony is volatilized as antimony sulfide, burned, and separated in a baghouse as antimony(III) oxide. The impure oxide is pelletized and melted in a rotary furnace. The cyclone slag contains about 1 % antimony [41]. (See also Section 6.2 and Fig. 2.)

6.2. Reduction of Oxide to the Metal

The oxides from volatilizing roasting, as well as other oxidized antimony materials, are reduced to the metal with carbonaceous materials. Occasionally oxide ores containing more than 50 % antimony are finely ground and also reduced. Sometimes the oxide must be treated beforehand to remove arsenic, but improved roasting techniques frequently make this unnecessary. The amount of carbon required for reduction depends on the composition of the oxide, ranging between 8 and 12 %. Pulverized charcoal, anthracite dust, or lean coke breeze are used [14].

$$Sb_2S_3 + 3\,C \rightarrow 2\,Sb + 3\,CO$$

$$Sb_2S_3 + 3\,CO \rightarrow 2\,Sb + 3\,CO_2$$

Different slag systems are in use. In the combined blast furnace/reverberatory smelting technology, as traditionally operated in China, a 40:30:20 $FeO:CaO:SiO_2$ slag is used. To prevent the loss of volatile Sb_2O_3, a sodium salt, such as soda (Na_2CO_3) or Glauber's salt (Na_2SO_4), is added to give a slag of low viscosity. Impurities such as copper and iron are converted to matte by adding sulfur, usually in the form of crude antimony. The slags can contain 5 – 20 % antimony, which must be recovered.

Figure 2. Antimony flowsheet for the smelter at Vinto, Bolivia [41]

Smelting of antimony oxide flue dust containing arsenic, such as is obtained by roasting ores, with sodium hydroxide produces metallic antimony.

$$2\,Sb_2O_3 + 3\,As_2O_3 + 18\,NaOH \rightarrow 4\,Sb + 6\,Na_3AsO_4 + 9\,H_2O$$

The arsenic dissolves in the alkaline slag [42–44].

The oxides are reduced in shaft, reverberatory, or short rotary furnaces. All types of furnaces require efficient precipitators and off-gas filters to remove volatilized antimony(III) oxide.

The pronounced reducing action in *shaft furnaces* does not produce pure metal but does yield slags containing a maximum of only 2.5 % antimony and usually less than 1 %. These slags can be used in glass manufacture. The furnaces have large height to diameter ratios, e.g., 6 : 1. The charge must be in the form of lumps or briquettes. The yield is between 95 and 98 %; the impure product contains 90 – 92 % antimony, 5 – 7 % iron, and arsenic and lead.

Reverberatory furnaces produce metal of comparatively high purity, but the slag is rich in antimony and requires further treatment. These furnaces are fed with high-grade ores that yield fairly small quantities of slag and with antimony-laden flue dust.

Stationary reverberatory furnaces have been largely replaced by *short rotary furnaces* in which the charge is very thoroughly mixed and rapidly melted. The rotary movement efficiently transfers heat to the charge. Tapholes are arranged at various heights in the furnace to allow molten metal, liquefied slag, and solid residues to be withdrawn. The great advantage of this process is that reduction in the furnace can be controlled so that the accompanying metals, such as lead, iron, and arsenic, are not reduced or are volatilized. This makes the refining simpler.

At the antimony smelter at Vinto, Bolivia, the oxide melt passes from the rotary furnace to reverberatory furnaces for reduction and final refining at 800 °C. Coal and sodium hydroxide are added. The final product contains 99.6 % antimony. If less pure, it can be alloyed with copper, nickel, or lead. The total antimony recovery rate for the smelter is 92 % [41]. The complete flowsheet is shown in Figure 2 [14, 45–49].

Mining, beneficiation, and metallurgical procedures have changed little in the past 35 years. No new technological developments that would affect productivity are foreseen for the future [50, 51]. Apart from some work on the thermodynamics of the slag compositions used in antimony smelting, most of the publications concerning smelting technology date from around 1950 [45–49, 52–57].

6.3. Direct Reduction to the Metal

In blast furnace smelting the charge is antimony(III) sulfide, either alone or mixed with antimony oxides. The molten sulfide is first oxidized by the air blast. The oxide formed reacts with unconverted sulfide to yield metallic antimony.

$$2\,Sb_2S_3 + 9\,O_2 \rightarrow 2\,Sb_2O_3 + 6\,SO_2$$

$$2\,Sb_2O_3 + Sb_2S_3 \rightarrow 6\,Sb + 3\,SO_2$$

$$3\,Sb_2S_3 + 9\,O_2 \rightarrow 6\,Sb + 9\,SO_2$$

In view of the many oxidation states through which the antimony must pass, this process is undoubtedly more complex than the equivalent lead and copper processes. It has been successfully practiced for many years in Mexico, Belgium, Great Britain, and Czechoslovakia. Best results are obtained with sulfide ores containing 25 – 30 % antimony. The main disadvantage of the direct process is that antimony compounds are volatilized; this has been offset by using high, slender smelting columns.

Standard practice favors low air pressures, e.g., 5.5 kPa at a flow rate of 1200 m^3/s. The antimony content of the mixed charge should be less than 20 %. Suitable fluxes are limestone, pyrite cinders, and ferrous slags. The required proportion of coke is about 15 %. The slag and the metal usually are separated in a heated forehearth.

The yield of antimony can be as high as 98 %, but not all of this is metal. Some leaves the shaft furnace as oxide, which must be trapped in filters. The metal is contaminated by iron, lead, and some copper and arsenic and must be refined (see Chap. 7) [19, 58].

6.4. Hydrometallurgical and Electrolytic Methods

Hydrometallurgical processing is suitable for some ores, particularly those containing gold, silver, and copper, and especially tetrahedrite, $Sb_2S_3 \cdot Cu_2S$ [59–62]. The high antimony content makes extracting the precious metals with cyanide difficult.

A number of methods have been proposed; however, most are plagued by unresolved problems. If sulfidic antimony ores are digested with *acids*, hydrogen sulfide is given off. Sulfuric acid does not digest the ores completely at 300 °C. Although hydrochloric acid is a better solvent and the antimony(III) chloride is adequately soluble, the problems involved in further processing have not been resolved. Cementation with iron, precipitation as the sulfide, and electrolysis have been investigated as means of separating the antimony. Explosive antimony is likely to form if electrolysis is used on antimony chlorides.

Antimony ores can be digested by alkalies. The mechanochemical leaching of antimony from Slovakian tetrahedrite concentrate in an attritor and the chemical leaching of the resulting solid residues were studied. The results indicate that recoveries of 52 – 100 % Sb, 60 – 85 % Hg and 50 – 96 % Ag can be achieved by using alkaline solutions of Na_2S for leaching of Sb and Hg. The dissolution of Sb from a Columbian stibnite concentrate in basic solutions of $Na_2S \cdot 9\,H_2O$ and NaOH gave a maximum Sb extraction of 94 % from a concentrate containing 30 % Sb with a mixture of 12.5 % Na_2S and 4.0 % NaOH [63].

The antimony can be reduced from the solutions electrolytically or by cementation on aluminum or zinc. Very pure rhombohedral antimony is obtained by electrolysis.

Any raw materials that are soluble in sodium sulfide, e.g., antimony glance or foundry prod-

ucts containing antimony sulfide, are suitable starting materials for antimony recovery by electrolysis. The solution is purified and then electrolyzed in diaphragm cells with iron or lead anodes and iron cathodes. The purity of the antimony is 96 – 99 %.

The source of all the valuable metals in the Sunshine Mine ore is an argentiferous tetrahedrite (a silver – copper – antimony sulfide), which cannot be broken down physically into its constituents. The tetrahedrite occurs reasonably free, and about 85 % can be floated into a high-grade concentrate after grinding to a relatively coarse size.

According to a publication from 1944 [64], the high antimony content precludes adoption of large-scale copper smelting for the concentrate, and lead smelting is just as unsuccessful because of the high antimony and copper contents and the presence of bismuth. Instead, the antimony is extracted from the argentiferous tetrahedrite by an alkaline sulfide solution. The residue consists of insoluble silver and copper sulfides. The antimony is recovered from the alkaline solution by electrolysis.

The steps are as follows:

1) The antimony is batch leached with hot concentrated sodium sulfide solution from milled tetrahedrite concentrate to give a solution containing about 250 g Na_2S and 50 g Sb per liter. The leaching time is 8 – 10 h at 100 – 103 °C.
2) After the residue settles, the supernatant solution is decanted. The residue is recovered by two-stage filtration with a repulping step between the stages. The pregnant solution is fed to the electrolytic section through two anolyte and two catholyte tanks.
3) The solution is batch electrolyzed in banks of diaphragm cells. The antimony is deposited at mild-steel cathodes. The electrolytic section consists of 96 cells in series, arranged in cascades of six.

During electrolysis, the antimony is deposited at the cathodes, and sulfur is concentrated in the anolyte, with the result that sodium polysulfide (Na_2S_3), sodium sulfite (Na_2SO_3), sodium thiosulfate ($Na_2S_2O_3$), and sodium sulfate (Na_2SO_4) form. The alkalinity of the anolyte decreases, whereas that of the catholyte increases.

Fresh anolyte is made up from a mixture of caustic soda solution and barren catholyte to be equivalent to 225 g NaOH per liter. It is discharged into the anolyte feed tanks in 7.5-t batches, and the same volume, having an alkalinity of about 175 g/L, is withdrawn to the regeneration section.

The fresh catholyte, also handled in batches, carries about 50 g of antimony and the equivalent of 250 g of NaOH per liter.

Catholyte is introduced near the bottom of each cell and withdrawn at the top. Because antimony depletion lowers the specific gravity, the weakest solution is drawn off and fed to the following cascade. The solution leaving the final cell in a cascade is pumped back to the catholyte feed tank, unless its antimony content has been reduced to the barren solution level of 8 – 10 g/L. The barren solution has an alkalinity equivalent of ≈ 280 g NaOH per liter. About 30 t of barren solution is withdrawn during each cycle, and the same amount of fresh pregnant solution is added to the feed tank.

The busbar current is 1500 A, producing a current density of 300 A/m^2. There is no gassing at the cathodes until the antimony content of the solution falls below 8 g/L. The voltage drop varies slowly between 2.5 and 3 V per cell, depending on the alkalinity of the anolyte, averaging about 2.65 V. The cathodes are stripped every three days.

The spent solutions from both the catholyte and anolyte cell banks are led to the regeneration circuit for treatment with barium sulfide solution. After the precipitated barium salts have been separated, the solutions are returned to the leaching circuit. The precipitated barium salts are mixed with coal and passed through a rotary kiln for reduction to a black ash containing barium sulfide.

The process is cyclic and regenerative, except that some barite must be supplied, and some caustic soda must be added to the anolyte to replace sodium lost with the copper residue.

The antimony is sold as unrefined granular cathode antimony containing 96 – 97 % antimony and 2 – 3 % arsenic. Copper, lead, iron, bismuth, and other elements make up less than 0.4 %. The small remainder is probably sodium sulfate. The flowsheet for the Sunshine Mining Co. electrolytic process is shown in Figure 3 [64].

Figure 3. Flowsheet for the Sunshine electrolytic antimony plant

In a method devised by the U.S. Bureau of Mines [65], the concentrate containing precious metals is smelted together with some iron. The metal obtained is deposited electrolytically at the cathode and refined. As much as 80 – 90 % of the antimony is recovered as metal; 80 – 94 % of the gold and 30 – 48 % of the silver pass into the anode mud (Fig. 4).

In another process the ore is smelted with soda and tetrahedrite and leached with lime. The antimony passes into solution as sodium thioantimonate, Na_3SbS_4. The arsenic is precipitated. If the ratio of sodium to sulfur in the electrolyte is 2 : 1 and the current density on the order of 1000 A/m^2, no diaphragms are needed; the current efficiency is 60 % [64–66].

Solvent extraction methods can be utilized for the selective recovery of antimony from solutions. A suitable application could be the recovery of antimony from solutions with a high copper content such as the electrolytes in electrolytical copper refining plants (see Chapter 6.5) [67].

Figure 4. Beneficiation of a concentrate containing precious metals [65]

6.5. Recovery from Byproducts

Lead and copper ores often contain antimony which is concentrated in byproducts and removed during the recovery of the main metal. Different treatments of the byproducts for the recovery of antimony are reported.

In the pyrometallurgical processing of *antimony-containing lead ores* about 90 % of the antimony is recovered in the lead. During refining, the antimony is oxidized, usually in reverberatory furnaces, into an oxide slag, called antimony skimmings. After the entrained lead has been liquated, skimmings are smelted together with coal and fluxes, frequently in short rotary kilns, to yield a crude antimonial lead.

In the Harris refining process, lead bullion is treated at 400 °C with a melt of sodium chloride, sodium monoxide, and sodium nitrate. Arsenic, tin, and antimony are converted into slags. The antimony-rich slag from the last Harris refining step contains the antimony as sodium antimonate. This caustic slag is treated hydrometallurgically with a weak NaOH solution. While the residue contains about 45 – 50 % Sb and can be sold as white sodium antimonate for the production of antimony metal or compounds, the filtrate is evaporated and the concentrated soda recycled to the Harris process [68].

Particularly in the case of bismuth-rich lead, lead bullion is cast into anodes and refined by an electrolytical process. The antimony is retained in the anode slime, together with the other undissolved metals: copper, arsenic, bismuth, and precious metals. A typical anode slime from a lead refining electrolysis contains 6 % Ag, 30 % Sb, 15 % Bi, 12 % Pb, and some Cu [69]. The anode slime is smelted under reducing conditions to give a lead alloy. The antimony is then removed by selective oxidation and subsequently recovered from the flue dust by another reducing smelting operation, which can be followed by oxidation to produce refined antimony oxide [69–72]. A flow sheet for the treatment of lead anode slime is given in Figure 5.

About 95 % of the antimony in lead ores is recovered in the form of antimony alloys, which are usually diluted with refined lead and sold as is [73]. These alloys are used mainly in lead – acid storage batteries.

The recovery of copper from antimony-containing sulfidic copper ores includes the following process steps: copper matte smelting, matte converting, fire refining, anode casting, and electrolytic refining. During the pyrometallurgical operations some of the harmful impurities of copper smelting such as antimony, bismuth, arsenic, lead, and others are removed in slag or as flue dust. Of these impurities antimony is the most difficult to remove [74].

The reported distributions of antimony into the different product phases of the pyrometallurgical unit operations vary widely. In the matte smelting process in the Outokumpu flash smelting furnace, 26 % of the antimony reports to the matte, 45 % to the slag, 13 % to the flue dust, which is recycled to the furnace, and 16 % to the flue dust bleed off [69]. Depending on the converting technology, most of the antimony from the charged copper matte reports to the slag and the blister copper, while only a smaller fraction is found in the flue dust [69, 75–77].

Antimony in copper smelter flue dust can be recovered during dearsenification or kept in the metallurgical circuit by recycling the flue dust to the furnaces for further enrichment. The particular composition determines how these flue dusts are processed; there are no standard procedures [14]. Slags from the converting section are usually recycled to the matte smelting furnace. The direct recovery of valuable metals from converting slags by reduction with carbon has been suggested [75, 78].

Much research has been undertaken into separating antimony from the copper before it is electrolytically refined. Different fluxes (e.g., alkali metal carbonates) and the thermodynamical conditions which influence the distribution of antimony between slag and metal phase in copper fire refining have been studied in detail [77, 79–84]. Still an appreciable amount of antimony remains in the cast anodes. In the electrolytical refining about 50 % of the antimony reports to the anode slime, while the rest accumulates in the electrolyte. The presence of Sb^{V} ions in the electrolyte seems to increase the amount of floating slimes in the electrolytic cells and thus has a negative influence on cathode quality [85]. During the cleaning of the electrolyte bleed-off stream, antimony is precipitated together with copper in the copper electrowinning cells and recycled into the pyrometallurgical process section [86]. Antimony can also be separated from

Figure 5. Basic flow sheet for lead anode slime treatment [69]

copper-containing solutions by solvent extraction or ion exchange [85, 87–93].

The chemical composition of anode slimes from electrolytical copper refineries varies over wide ranges (Table 3). The antimony content is up to 9.5 % and is generally higher when secondary raw materials are charged in the smelting section instead of concentrates. As numerous as the compositions of the slimes are the technologies which can be applied for their treatment [94–97]. The aim of the different treatment methods is mainly the recovery of precious metals Such as gold, silver, and the platinum group metals. Figure 6 shows a selection of different approaches for the treatment of anode slimes. The slags of the Doré furnace are one possibility for the recovery of antimony metal [94].

7. Refining

Antimony from the smelter usually contains iron, arsenic, tin, zinc, copper, lead, and bismuth. Several processes are used to produce a commercial grade containing $\geqq$ 99 % antimony and $\leqq$ 0.3 % arsenic. Iron, arsenic, and tin are removed by melting with caustic soda. A slow current of air is passed over the metal – caustic soda bath. Generally the caustic soda is renewed once during purification. At a bath temperature of 950 °C and a total air flow of 500 m^3/kg arsenic is reduced in two hours to a residual 0.05 % and iron is reduced to a residual 0.005 %. Sodium nitrate can be used instead of the combination of caustic soda and air.

Although the maximum permissible *arsenic* content is 0.3 %, a maximum of 0.1 % is often specified. The measures taken to ensure such a low content must begin in the earliest beneficiation stages (Chap. 5 and Section 6.1). The

Figure 6. A selection of different approaches to the treatment of anode slimes [96]
TBRC = top-blown rotary converter

methods are well known, and some of them are standard practice [4, pp. 38 – 45].

To a great extent arsenic can be prevented by selective flotation from entering the concentrate [27, 98, 99]. About 88 % of the arsenic can be volatilized from concentrates and antimony oxide flue dust by roasting in the presence of steam at 475 – 500 °C. The associated antimony losses are limited to 10 – 45 %. If arsenic – antimony oxides are treated with hot caustic soda, the arsenic trioxide passes into solution as arsenite, whereas the antimony oxide is not changed. One to six kilograms of caustic soda is required for each kilogram of arsenic. The arsenic is completely separated from the antimony [4, p. 44].

Electrostatic precipitators offer means of separating arsenic from antimony at elevated temperature because gaseous arsenic trioxide can

pass through them, whereas solid antimony trioxide precipitates. The best results, only 0.66 – 0.79 % arsenic in the antimony trioxide, are obtained for a gas-inlet temperature of 620 – 650 °C and an outlet temperature of 430 – 470 °C.

The removal of *lead* from crude antimony is of less importance because most antimony produced is used in lead alloys. In any case, separation is difficult owing to the affinity between the two metals. Suitable methods are electrolysis, chloridization, and sulfidization.

Liquid antimony containing lead and arsenic can be refined in two subsequent stages. Lead, as well as iron, tin, and copper, are preferably removed in the first stage by means of sulfide-rich antimony slags. The best conditions for the removal of iron from liquid antimony are simultaneous oxidation and sulfidization with antimony slags containing 70 mol % Sb_2O_3. Arsenic generally does not react with Sb – S – O slags. A low refining temperature (e.g., 973K) is preferable. A possible second refining stage is the application of Na_2CO_3 – Sb_2O_3 slags, which preferentially dissolve arsenic [100, 101].

A number of methods have been proposed, and occasionally used, for electrolytic separation of lead from antimony on an industrial scale [4, 59]. Although pure antimony is obtained from alkaline thioantimonite solutions, the current efficiency is low, and there are difficulties, including the formation of an insoluble film at the anode. Under some circumstances, electrolysis of antimony chloride gives rise to explosive antimony.

However, the only electrolysis that gives better results involves antimony trifluoride. The crude metal can be refined in a sulfate – fluoride solution. Even if the percentage of lead is quite high, lead-free antimony is obtained at the cathode. The excess sulfuric acid in the electrolyte precipitates the lead as lead sulfate, which passes into the anode mud. The energy consumed is 320 kWh/t. Arsenic must be removed beforehand; otherwise, it also deposits on the cathode. Operational details are given in [60].

It is claimed [4, pp. 46, 47], [102] that antimony of 99.2 % purity is produced if 96.5 % antimony with lead as the main impurity is treated with chloride at 1100 °C. If antimony rich in lead is fused with a sulfur flux, the lead, as well as zinc, copper, and bismuth, is removed almost completely [4, p. 48]. This method is simpler and cheaper than electrolysis.

Electrolytic refining in molten sodium and potassium chloride at 750 – 800 °C is said to yield pure antimony. *Iron* can be reduced rapidly to a residual 50 – 90 ppm. Lead and copper are difficult to remove; therefore, the antimony should be purified pyrometallurgically beforehand.

8. Fine Purification [14]

The antimony used as a solvent for extremely pure silicon must also be extremely pure. Silver, aluminum, chromium, copper, iron, magnesium, manganese, and nickel can be removed almost completely by subliming commercial antimony (99.5 – 99.9 % Sb). However, almost all of the arsenic, lead, tin, and sulfur enters the sublimate, and the product is often contaminated with carbon and silicon. If commercial antimony is alloyed with 0.5 – 4 % manganese, the sublimate is free from tin and largely free from sulfur. If 1 – 2 % aluminum is used in addition to the manganese, the lead and arsenic contents are also reduced substantially. However, this procedure is not effective unless the rate of sublimation is reduced, to one third in the first case or one tenth in the second. This refining by sublimation is shown schematically in Figure 7.

Figure 7. Sublimation refining

There is growing demand for extremely pure antimony. It is derived from previously purified metal or from antimony(III) oxide. (Table 4 shows typical compositions of the starting materials.) The impurities remaining are removed by physical, chemical, and metallurgical methods, including distillation [104], ion exchange [105], liquid – liquid extraction [106], precipitation of intermetallic compounds [8], and zone melting [107–113].

Table 4. Spectrographic analysis of antimony regulus and of the antimony trioxide obtained by oxidation [103]

Element	Contents, ppm unless otherwise indicated	
	Antimony regulus	Antimony trioxide

S	230	106
Sb	99.5 %	> 83.38 %
Sb as Sb_2O_3	–	> 99.8 %

A method described by M. Tanenbaum involves dissolving antimony of 99.8 % purity in hydrochloric acid, repeatedly distilling the antimony trichloride obtained to remove the arsenic, and reducing the purified antimony trichloride with iron pentacarbonyl. Zone melting then gives a product of 99.999 % purity [112].

A process patented by M. Wilhelm uses hydrogen to reduce antimony pentachloride that has been purified by repeated distillation at 700 – 900 °C in an atmosphere of argon. The yield is $\leqq$ 70 % [113].

Antimony can be separated from numerous impurities by fractional distillation of the anhydrous trichloride or pentachloride [104]. Platinum, gold, silver, manganese, nickel, cobalt, and copper remain behind in the residue. If the heating is carried out carefully, the lead, bismuth, zinc, thallium, and cadmium also remain in the residue. Aluminum chloride, arsenic trichloride, and tin(IV) chloride pass completely into the first fractions, whereas tin(II) chloride remains behind. Currently only hydrochloric acid solutions are distilled. Under these circumstances, arsenic trichloride distills at temperatures below 110 °C. Because distillation above 110 °C results in considerable loss of antimony, the temperature must be kept slightly under 110 °C.

Ileva and Vigdorovich stressed the effectiveness of chemical methods in separating arsenic from antimony and in lowering antimony's heavy metal content. Antimony trichloride is prepared by dissolving technical-grade antimony in hydrochloric acid and is hydrolyzed to give antimony trioxide, which is reduced with pure sucrose. The metal is then purified by zone melting to give a product with 99.995 % antimony in 51 – 53 % yield [114].

One rather complex procedure consists of the following: (1) dissolving technical-grade antimony in hydrochloric acid, (2) purifying the antimony trichloride obtained by fractional distillation, (3) converting the purified antimony trichloride into antimony trisulfide, (4) dissolving the sulfide in pure hydrochloric acid, (5) distilling the antimony trichloride, (6) hydrolyzing the trichloride into antimony trioxide, and (7) reducing the oxide with hydrogen. The purity of the antimony exceeds 99.998 %, but the yield is low because of the large number of operations.

Very pure antimony trichloride can be purified further by hydrolysis to antimony trioxide with extremely pure water. The trioxide is reduced with purified hydrogen, first at about 600 °C and then at a somewhat higher temperature [8].

The recrystallization of chloroantimonic acid (H_2SbCl_6) efficiently removes final traces of iron [104].

Ion exchange removes cobalt, nickel, zinc, and lead [115, 116]. However, hydrolysis can result in less than quantitative elution.

Liquid – liquid extraction offers a means for refining antimony [106], e.g., by purifying acidic solutions of antimony with alkylphosphoric acid or separating copper, iron, and lead from hydrochloric acid solutions by extraction with ethyl acetate. Pentavalent antimony dissolved in hydrochloric acid can be extracted by dibutyl ether, amyl alcohol, hexyl alcohol, *n*-octyl alcohol, and diisoamyl ether. However, liquid – liquid extraction is seldom used in practice.

The effectiveness of zone melting, usually the last stage in fine purification, depends on the impurities present. Arsenic, tin, and bismuth have unfavorable distribution coefficients (Table 5) and are difficult to remove by zone melting.

Arsenic must be removed completely in the preceding purification steps. Lead and germanium are easier to remove. In one case, seven passages of the melted zone dropped the nickel, lead, silver, and copper contents to one tenth their original values [111, 112]. The impurity levels, in ppm, are reduced to < 0.5 Ag, < 5 As, < 1 Bi, 0.5 Cu, < 1 Fe, < 5 Ni, 2 Pb, and < 2 Sn [103].

Table 5. Distribution coefficients in antimony [103]

As	0.64	Pb	0.06
Sn	0.3	Ge	< 0.06
Bi	0.2		

Very pure antimony is produced in three grades: > 99.99 % (4N), > 99.999 % (5N), and > 99.9999 % (6N). Very pure antimony for electronic applications has to be at least of an 99.999 % Sb quality. Qualities of 99.999999 % Sb (Mikuni Smelting & Refing Co., Japan) and of 99.9999 % Sb (Preussag AG Metall, Cominco American Corp., USA) are also available.

9. Recovery of Antimony Oxide

Antimony(III) oxide is being used as flame retardant in an increasing quantities. It is produced mostly by roasting sulfidic antimony ores or other antimony-containing raw materials. The main techniques applied are described in Chapter 6.1. To recover antimony oxide of higher purity, especially for the separation of arsenic and antimony oxide, selective volatilization of the more volatile arsenic trioxide and selective condensation of the less volatile antimony tetroxide at high temperatures, leaving arsenic trioxide to condense out at lower temperatures, can be applied [19, 36]. Antimony trioxide can also be recovered from complex antimony sulfide ores by reaction with calcium chloride. The reaction takes place in an oxidizing atmosphere at about 500 °C.

$$Sb_2S_3 + 3\,CaCl_2 + 6\,O_2 \rightarrow 2\,SbCl_3 + 3\,CaSO_4$$

More than 90 % of the antimony is volatilized as $SbCl_3$, which can be purified by distillation and hydrolyzed to Sb_2O_3. The flow sheet is shown in Figure 8 [32].

10. Antimony Alloys and Intermetallic Compounds

Antimony is a component of many lead and tin alloys (→ Lead Alloys, → Tin, Tin Alloys, and Tin Compounds). These alloys are important materials for making bearings (→ Semiconductors) and solders (→ Lead Alloys).

The intermetallic compounds AlSb [*25152-52-7*], GaSb [*12064-03-8*], and InSb [*1312-41-0*] (→ Lead Alloys) are important. Zinc antimonide, ZnSb, has interesting semiconductor and thermoelectric properties; cadmium antimonide, CdSb, has interesting semiconductor properties. Antimony is used to dope very pure germanium, silicon, and gallium arsenide to produce *n*-type semiconductors.

11. Antimony Compounds

Antimony can be trivalent or pentavalent in compounds. Both exist in antimony(IV) oxide, Sb_2O_4, and presumably in the deep violet haloantimonates(IV), such as $Cs_2(SbCl_6)$. The pentavalent compounds, as well as most of the trivalent ones, are hydrolyzed by water to form antimony salts, e.g., SbOCl, and hydrated oxides. The only halides of antimony that have any industrial significance are the chlorides and fluorides.

Mixed antimony(V) chloride fluorides and bromide fluorides exist, but antimony pentabromide does not. The tribromide, $SbBr_3$, is chemically similar to the trichloride. Stable complex halides are known, mainly hexahaloantimony anions of the types $[SbX_6]^{3-}$ and $[SbX_6]^{-}$.

11.1. Antimony Chlorides

Antimony trichloride [*10025-91-9*] (antimony chloride, butter of antimony, caustic antimony), $SbCl_3$, M_r 228.1, *mp* 73 °C, *bp* 223 °C, ϱ 3.064 g/cm^3 at 26 °C, is soft, crystalline, colorless, and very hygroscopic. It is soluble in the usual organic solvents, including benzene, carbon disulfide, carbon tetrachloride, acetone, and ethanol. Only highly concentrated aqueous solutions are stable. Dilution causes antimony(III) chloride oxide, SbOCl, to precipitate. The addition of

Figure 8. Chloridization process

more water causes further hydrolysis to take place, forming hydrated antimony(III) oxide. Antimony trichloride forms complexes with numerous compounds, some having a striking deep color.

Antimony trichloride is an intermediate in the production of other antimony compounds, a catalyst in organic chlorination and polymerization reactions, and a vitamin A reagent. Large quantities are consumed in rendering textiles, plastics, and other combustible substances flame retardant or self-extinguishing.

Although manufacture from antimony metal and chlorine is expensive, it is feasible on a small scale. The best procedure is to react chlorine with antimony metal in liquid antimony trichloride or concentrated hydrochloric acid. In the first case the temperature can be as high as

200 °C. Equally good results are obtained by dissolving antimony oxides in hot, concentrated hydrochloric acid. Distillation of the crude product or its solution in strong hydrochloric acid in the presence of some metallic antimony or iron (to reduce antimony(V) and iron(III) compounds) then yields pure antimony trichloride.

Stibnite is usually digested in concentrated hydrochloric acid. The antimony passes into solution, whereas the arsenic largely remains in the residue. Disadvantages are the noxious hydrogen sulfide given off and difficulties in heating the strongly acidic solutions.

Antimony chloride oxide (oxychloride), [*7791-08-4*], SbOCl, is a white crystalline powder. It is precipitated by hydrolysis when concentrated solutions of antimony trichloride in water or hydrochloric acid are diluted. Because other chloride oxides, e.g., $Sb_4O_5Cl_2$, also form, reaction conditions must be controlled carefully. Antimony chloride oxide is an intermediate in the production of antimony salts and is used in smoke-producing agents.

Antimony pentachloride [*7647-18-9*], $SbCl_5$, M_r 299.1, *mp* 4 °C, *bp* 140 °C, ϱ 2.34 g/cm^3 at 20 °C, is a pale yellow fuming liquid of unpleasant odor. It can be produced by saturating molten antimony trichloride with chlorine, followed by vacuum distillation. Other methods are the direct chlorination of antimony and the chlorination of antimony oxides or sulfides.

Antimony pentachloride, which easily dissociates and tends to chelate, acts as a chlorine donor in the chlorination of organic compounds. It is also used as a polymerization catalyst.

11.2. Antimony Fluorides

Antimony trifluoride [*7783-56-4*], SbF_3, M_r 178.8, *mp* 292 °C, *bp* 319 °C, ϱ 4.39 g/cm^3, is a colorless compound that crystallizes readily and volatilizes at room temperature. If it is exposed to atmospheric moisture, hydrogen fluoride is given off. In organic solvents it is less soluble than the chloride, but both dilute and concentrated aqueous solutions are stable. Antimony trifluoride forms complexes with inorganic compounds. It is an important fluorinating agent, replacing chlorine or bromine by fluorine in both inorganic and organic compounds. It is especially useful for converting acid chlorides to the fluorides. However, if the halogen group in organic compounds is not very reactive, fluorination is quite sluggish. The rate of reaction can be increased considerably by adding some antimony pentachloride or bromine, in order to form antimony(V) bromide fluorides. Antimony trifluoride is used in the production of pottery and porcelain, and potassium fluoroantimonate(III) is a mordant in dyeing.

Antimony pentafluoride [*7783-70-2*], SbF_5, M_r 216.8, ϱ 2.99 g/cm^3, is a colorless oily liquid at room temperature. Under atmospheric pressure at 7 °C it solidifies to a crystalline mass; it boils at 150 °C. The solid dissolves in water with a violent reaction. The pentafluoride carbonizes and fluorinates organic substances. The chlorine in chlorinated hydrocarbons is replaced by fluorine. Many inorganic substances form complexes with antimony pentafluoride.

Antimony pentafluoride is prepared by treating antimony pentachloride with excess anhydrous hydrogen fluoride. The antimony pentafluoride is separated from the volatile byproducts by fractional distillation. It can also be prepared by allowing fluorine to react with antimony powder or molten antimony trifluoride.

The main use of antimony pentafluoride is as a fluorinating agent.

11.3. Antimony Tribromide

Antimony tribromide [*7789-61-9*], $SbBr_3$, M_r 361.51, *mp* 96.6 °C, *bp* 280 °C, ϱ 4.15 g/cm^3, is a white solid. It is used as a mordant.

11.4. Antimony Triiodide

Antimony triiodide [*7790-44-5*], SbI_3, M_r 502.50, *mp* 167 °C, *bp* 401 °C, ϱ 4.78 g/cm^3, is a red solid that hydrolyzes readily and forms complex ions. It adds to ethers, aldehydes, and thiols. Antimony triiodide is prepared by reacting iodine with antimony or antimony sulfide in an organic solvent. The triiodide is used in medicine.

11.5. Antimony Oxides

Antimony trioxide [*1309-64-4*], Sb_2O_3, M_r 291.52, has two modifications: senarmontite be-

low 570 °C, ϱ 5.25 g/cm^3, and valentinite (white antimony, antimony bloom) above 570 °C, ϱ 5.7 g/cm^3. The melting point is 656 °C. The commercial product is a white crystalline powder with a density of 5.2 – 5.8 g/cm^3. On heating, it becomes yellow but turns white again on cooling. Antimony trioxide dissolves in acids and alkalies. For uses see Chapter 13.

Antimony trioxide can be produced by roasting antimony trisulfide, by burning antimony in air or oxygen, by alkaline hydrolysis of antimony halides (trichloride, tribromide, or triiodide), and by hydrolysis of antimony trisulfide with superheated steam. The production of antimony trioxide from antimony trisulfide during ore processing is described in Section 6.1.

Antimony tetraoxide [*1332-81-6*], Sb_2O_4, is a white nonvolatile powder that is soluble in alkalies but not in acids. Its density can differ considerably according to the duration of heating during preparation: 4.07 – 7.5 g/cm^3. Cervantite has a density of 4.07 g/cm^3. Antimony tetraoxide is obtained by roasting antimony trisulfide in a current of air or by heating antimony trioxide at 300 – 400 °C in air. The tetraoxide is used in ceramics.

Antimony pentoxide [*1314-60-9*], Sb_2O_5, is a whitish yellow powder. On heating, it first turns deep yellow; above 300 °C it turns from brownish yellow to brown but becomes paler above 380 °C. Its density ranges from 3.78 to 7.86 g/cm^3. Antimony pentoxide is sparingly soluble in water but readily soluble in alkalies.

The pentoxide can be produced by the action of strong oxidizing agents on metallic antimony or antimony trioxide. Hydrated antimony pentoxide can be produced by the hydrolysis of antimony pentachloride. The hydrate can be dried without difficulty.

11.6. Antimonic Acid and Antimonates

Many years ago antimonic acid was thought to have ortho, pyro, and meta forms, but these have all turned out to be only hydrated antimony oxide, primarily colloidal and differing in water content and solubility in acids and bases.

Potassium antimonate [*12208-13-8*], $K[Sb(OH)_6]$. Heating antimony pentoxide with excess potassium hydroxide produces rubbery, granular, or crystalline products. If the substance is recrystallized from a little water, deliquescent mammilated crystals form. Treated with copious cold water or boiled together with a small quantity of water, they are converted into potassium hexahydroxyantimonate, $K[Sb(OH)_6]$, which is sparingly soluble in cold water but somewhat more soluble in warm water. Solutions precipitate sodium as the sparingly soluble sodium hexahydroxyantimonate, $Na[Sb(OH)_6]$. This reaction is used for the detection of sodium.

Sodium hexahydroxyantimonate [*12339-41-2*] was formerly thought to be sodium pyroantimonate, $Na_2H_2Sb_2O_7 \cdot 5\ H_2O$. The hexahydroxyantimonate is prepared by melting antimony or antimony oxides with excess sodium nitrate. It is used as an opacifier for glass and enamel.

According to X-ray diffraction analysis, the hydrated antimonates(V) of magnesium, cobalt, and nickel are hexahydroxyantimonates, $[M(H_2O)_6][Sb(OH)_6]_2$, M = Mg, Co, or Ni.

11.7. Antimony Sulfides

Antimony trisulfide [*1345-04-6*] (stibnite), Sb_2S_3, M_r 339.70, *mp* 550 °C, ϱ 4.64 g/cm^3, has a black crystalline modification and an unstable red-orange modification. If both occur together, the mixture can be carmine or brownish red.

Antimony trisulfide is soluble in alkalies and in concentrated, but not dilute, hydrochloric acid. It also goes into solution if it is boiled in alkali carbonate solutions. However, it precipitates as a reddish-brown powder, of nondefinite oxygen content (kermesite), when the solution is cooled. It forms thioantimonates if it is dissolved in alkali-metal sulfides. Antimony trisulfide is a starting material for the production of antimony and antimony compounds. For specific uses see Chapter 13.

Antimony pentasulfide [*1315-04-4*], Sb_2S_5, M_r 403.82, is an orange to dark red powder. It is doubtful whether stoichiometric Sb_2S_5 exists, because the preparations contain free sulfur and have variable composition. Antimony pentasulfide is insoluble in water but soluble in alkalies and alkali-metal carbonates. Thioantimonates are formed if the pentasulfide is dissolved in alkali sulfides; the most important of these is Schlippe's salt [*1317-86-8*], sodium tetrathioantimonate, $Na_3SbS_4 \cdot 9\ H_2O$, which is

produced on a commercial scale by melting stibnite, sodium sulfide, and sulfur together. Antimony pentasulfide can be obtained from Schlippe's salt by reaction with hydrochloric acid.

11.8. Antimony Sulfate

Antimony sulfate [*7446-32-4*], $Sb_2(SO_4)_3$, M_r 531.74, ϱ 3.62 g/cm^3, is a hygroscopic compound in the form of needles with a silken sheen. When antimony or antimony trioxide, trisulfide, or oxychloride is dissolved in hot sulfuric acid, antimony sulfate or antimonyl salts are recovered. Antimony sulfate is used in the manufacture of explosives and in fireworks.

11.9. Stibine

Stibine [*7803-52-3*], antimony hydride, SbH_3, M_r 124.77, is a poisonous, foul-smelling gas of density 5.685 g/L (STP). The liquid boils at −88.5 °C. The gas is slightly soluble in water, soluble in alcohol, and very soluble in CS_2. Its formation is endothermic, ΔH_f = 140 kJ/mol, and it easily decomposes to hydrogen gas and antimony metal. Stibine is used to prepare *n*-type silicon semiconductors.

11.10. Organometallic Compounds

Organic compounds of antimony are known for the antimony oxidation states + 3 (SbR_3, R_2SbX $RSbX_2$, and + 5 (SbR_5, R_4SbX, R_3SbX_2, R_2SbX_3, $RSbX_4$), and the six-coordinate anions $[SbR_6]^-$). Organodistibines, $R_2Sb\text{-}SbR_2$, oligomeric and polymeric compounds with more than one Sb – Sb bond, $(RSb)_n$, and an aromatic organoantimony derivative, stibabenzene, have been described. A large number of derivatives of the stibonic acids, $RSbO(OH)_2$, and the stibinic acids, $R_2SbO(OH)$, have also been investigated [117–120].

Tertiary stibines, SbR_3, are usually prepared by Grignard alkylations of $SbCl_3$, by reaction of antimony trihalides with organolithium compounds, or by alkylation of Sb_2O_3 with trialkylaluminum in hexane. An example of the last is the preparation of $Sb(C_4H_9)_3$ [121]. Direct synthesis from Sb and organic halides, first used in 1850, is used to prepare $Sb(CF_3)_3$ from Sb and CF_3I at 170 °C [122]. Trialkylstibines are air-sensitive, the lower alkyl derivatives are even pyrophoric. $Sb(CH_3)_3$ is a liquid boiling at 79 – 81 °C under 101.3 kPa. $Sb(C_6H_5)_3$, *mp* 45 – 58 °C, *bp* 185 °C under 40 Pa, and other triarylstibines are more stable. The triorganylantimonys, SbR_3, react with halogens in an oxidative addition reaction to form triorganoantimony dihalides and with alkyl halides to produce the stibonium halides $[R_3SbR]^+X^-$. They also react with transition metal complexes to form R_3Sb – transition metal complexes containing metal – antimony bonds. The triorganylantimonys, especially $Sb(C_6H_5)_3$, are used as cocatalysts, antioxidants for certain organic compounds, corrosion inhibitors for steel, flame retardants for transparent resins, and an antifogging reagent in color film development [117].

The organoantimony(III) halides R_2SbX and $RSbX_2$ are made by pyrolysis of triorganoantimony dihalides and diorganoantimony trihalides, respectively, or by redistribution between SbX_3 and R_3Sb or R_2SbX. For example, $(C_6H_5)_2SbCl$ and $C_6H_5SbCl_2$ are synthesized by reaction of Ph_3Sb and $SbCl_3$ in the appropriate molar ratios [123]. $(C_6H_5)_2SbCl$, *mp* 68 – 70 °C is also formed from $SbCl_3$ and $Sn(C_6H_5)_4$ [124]. Only Grignard reagents with bulky alkyl groups, (R = *tert*-C_4H_9) are useful for stepwise alkylation reactions of $SbCl_3$ to give, for example, $(Me_3Si)_2CHSbCl_2$ [125] or tBu_2SbCl [126] selectively.

Addition of halide ions to organoantimony(III) halides results in the formation of $[R_2SbX_2]^-$, $[(RSbX_3)_2]^{2-}$ or $[RSbX_4]^{2-}$ [127]. Diorganoantimony cations, R_2Sb^+, are stabilized in adducts with donor molecules [128]. Diorganoantimony anions, R_2Sb^-, are formed by metalation of R_2SbH with BuLi [129].

R_2SbX and $RSbX_2$ compounds where X is a group other than halogen are also known. Hydrolysis of R_2SbCl leads to $(R_2Sb)_2O$, e.g., $[(C_6H_5)_2Sb]_2O$, *mp* 78 – 80 °C, and hydrolysis of $RSbCl_2$ leads to $(RSbO)_n$, e.g., $(RSbO)_4$ [R = $(Me_3Si)_2CH$] [130]. Esters of organic acids, such as $(C_6H_5)_2SbOOCCH_3$, *mp* 127 – 133 °C [131]; mercaptans, R_2SbSR or $RSb(SR)_2$; and

compounds with Sb–N, Sb–P, and Sb–metal bonds are known [117].

Pentamethylantimony, $Sb(CH_3)_5$, obtained from $(CH_3)_3SbBr_2$ and methyllithium, is a very reactive liquid, *bp* 130 – 131 °C under 101.3 kPa, which sometimes explodes during distillation [132]; the corresponding phenyl derivative, $Sb(C_6H_5)_5$, *mp* 164 – 172 °C, made by reacting $(C_6H_5)_4SbBr$ with phenyllithium, is much more stable [133].

Tetraalkyl- and tetraarylantimony compounds, R_4SbX, are known as stibonium salts. $(CH_3)_4SbF$, *mp* 50 °C, is made from $Sb(CH_3)_5$ and $(CH_3)_3SnF$ in ether [134], and $(C_6H_5)_4SbCl$, *mp* 202 – 205 °C, is the product of the reaction between $Sb(C_6H_5)_3$, $AlCl_3$, and C_6H_5Cl [135].

The alkoxides $(CH_3)_4SbOR$ have been prepared from $Sb(CH_3)_5$ [134]. $Sb(CH_3)_5$ can also be cleaved by mercaptans to form $(CH_3)_4SbSR$ [136] or by HN_3, HCN, or HSCN to form the corresponding tetramethylantimony azides, cyanides, or thiocyanates [137]. $Sb(C_6H_5)_5$ reacts with LiC_6H_5 in ether to form a white powder, $Li[Sb(C_6H_5)_6]$, which melts at 185 °C [133, 138].

Compounds of the type $RSbX_4$ (R = aryl) are prepared by chlorination of $RSbCl_2$ with Cl_2. They are usually converted to stibonic acids. $(C_6H_5)_2SbF_3$ is obtained by fluorination of $(C_6H_5)_2SbF$ with XeF_2 [139], and $(CH_3)_2SbCl_3$ is prepared by chlorination of $(CH_3)_2SbCl$. Other alkyl derivatives are obtained by the chlorination of distibines, $R_2Sb–SbR_2$ [140]. Trialkyl- and triarylantimony dihalides R_3SbX_2, prepared by the direct halogenation of SbR_3 compounds, are quite stable substances. They decompose on heating to form R_2SbX and RX [141].

Older references describing the existence of diazene analogues, RSb=SbR, are erroneous. However, recently a sterically protected distibene, RSb=SbR, R = 2,4,6-$[(Me_3Si)_2CH]_3C_6H_2$, was synthesized [142]. Compounds like $(CH_3Sb)_n$ are polymeric, and $(C_6H_5Sb)_6$, a molecule whose core is a six-membered ring of antimony atoms in a chair configuration, is hexameric [143]. Mono(*tert*butyl)antimony is tetrameric, $(tert\text{-}C_4H_9Sb)_4$ [126]. Compounds formed in the reactions of $RSbCl_2$ or $(RSbO)_n$ derivatives with primary arsines, or by reduction of arylarsonic acids or arylarsine oxides with antimony compounds, and containing As–Sb bonds and most probably polymeric were used as chemotherapeutics [144]. Tetraorganodistibines, $R_2Sb–SbR_2$, for example, $(CH_3)_2SbSb(CH_3)_2$ [145], are obtained by the action of organic free radicals upon metallic antimony mirrors. $(C_6H_5)_2SbSb(C_6H_5)_2$ is obtained from $Sb(C_6H_5)_3$ and sodium in liquid ammonia [146].

Stibabenzene, a reactive two-coordinate organoantimony compound, was the first example of a new class of organoantimony compounds [147]:

A distibabutadiene R'RC=Sb–Sb=CRR' (R = Me_3SiO, R' = 2,4,6-tBu$_3C_6H_2$) is formed by reaction of R'COCl with $Li[Sb(SiMe_3)_2]$ [148]

Stibonic acids, $RSbO(OH)_2$, R = aryl, are prepared from $SbCl_3$ by the diazo reaction with RN_2Cl and subsequent hydrolysis and are amorphous solids. Methylstibonic acid, $(CH_3SbO_2)_n \cdot m\ H_2O$ is formed by hydrolysis of $CH_3Sb(OCH_3)_4$ [149]. The dialkylstibinic acids, $R_2SbO(OH)$, are prepared by hydrolysis of the corresponding R_2SbCl_3 derivatives, whereas diphenylstibinic acid is made from $Sb(C_6H_5)_3$ by oxidative cleavage with NaOH and H_2O_2 [150]. The anhydride of diphenylstibonic acid is a cage compound $(Ph_2Sb)_4O_6$ [151]. *p*-Aminophenylstibonic acid is an ingredient of neostibosan, a drug for the treatment of oriental sore (leishmaniasis) [152]. Orthoesters of diarylstibinic acids are fungicides and bactericides, used in paints, plastics, and fibers [153].

Aliphatic and aromatic derivatives of stibine oxides, R_3SbO, and their hydrates, $R_3Sb(OH)_2$, are prepared by hydrolysis and subsequent dehydration of R_3SbCl_2. For example, $(CH_3)_3Sb(OH)_2$ is prepared by hydrolysis of $(CH_3)_3SbCl_2$. The hydrate loses water above 110 °C to give $(CH_3)_3SbO$ [154]. Triphenylstibine oxide $(C_6H_5)_3SbO$ is dimeric in the solid state [151].

12. Chemical Analysis

The presence of antimony can be demonstrated by the Marsh test. There are a number of classical gravimetric and volumetric methods for determining antimony. A popular colorimetric method is based on a complex between rhodamine B and antimony. Instrumental methods for traces of antimony include polarography, emission spectrography, neutron activation, and atomic absorption [155].

13. Uses

The uses of antimony can be divided into three categories: uses in alloys, uses in the oxide form, and other uses of antimony chemicals. For the U.S. market the reported industrial consumption of primary antimony by products is given in Table 6. About 50 % of the primary antimony production is used for flame retardants in plastics, while only about 20 % is used in metallic products. The former main application of antimony as an alloying element in lead alloys for the production of lead – acid batteries is declining, but most of the antimony still in use for this purpose originates from the recycling of used batteries, which is not included in the table. One product of the recycling process is a lead – antimony alloy, which is upgraded by the addition of pure lead and reused for the production of batteries.

Antimony Metal. Owing to its poor mechanical properties, antimony metal is not used directly but is used in numerous alloys, primarily with lead and tin.

Antimonial (Hard) Lead (see also → Bearing Materials). The addition of antimony to lead increases the tensile strength of cold-rolled lead from approximately 16.6 to approximately 32.1 MPa for an 8 % antimony alloy. Uses include storage-battery grids (7 – 12 % Sb), small-arms ammunition (12 – 15 % Sb), and cable sheathing and lead pipe (1 to 9 % Sb). Lead pipe is used in many applications that require acid-resistant pipe coils.

Antimonial lead (1.5 – 3 % Sb) is used in the grid plates, straps, and terminals of lead – acid batteries. The addition of antimony to lead improves the fluidity, making the casting of battery grids easier; moreover, the tensile strength is increased, and the thin grids are able to withstand the stresses imposed by the charging and discharging reactions. There is also an improvement in the electrochemical stability of the lead.

Table 6. Industrial consumption of primary antimony in the United States by product [20]

Product	Consumption	
	t/a	%
Metal products		
Antimonial lead[a]	1170	8.7
Bearing metal and bearings	45	0.3
Solder	226	1.7
Others[b]	1150	8.5
Total	2600	19.3
Nonmetal products		
Ammunition primers	20	0.1
Ceramics and glass	1080	8.0
Pigments	824	6.1
Plastics	1220	9.0
Others[c]	159	1.2
Total	3300	24.4
Flame retardants		
Adhesives	344	2.5
Plastics	6610	49.0
Rubber	342	2.5
Textiles	247	1.8
Others[d]	7	0.1
Total	7550	55.9
Grand total	13500	100

[a] Antimonial lead from secondary sources (recycling of lead batteries) not included.
[b] Includes ammunition, cable covering, castings, sheet and pipe, and type metal.
[c] Includes fireworks and rubber products.
[d] Includes paper and pigments.

Babitt Metals. Tin-based babbitts consist of ternary tin – antimony – copper alloys or quaternary tin – antimony – copper – lead alloys containing 4.5 – 14 % Sb and are used for low-load bearings that have good antiseizure properties and corrosion resistance but low fatigue strength.

Lead-based babbits are alloys of antimony, tin, and lead containing 8 – 15 % Sb, and may contain 1 – 3 % As (see → Soldering and Brazing). They are used for heavy-duty bearings where fatigue resistance is important, e.g., in railways.

Type Metals. Alloys of lead and antimony containing 2.5 – 25 % Sb are used in the printing industry. Antimony lowers the casting temperature, increases the hardness and minimises the shrinkage during freezing.

Brittania metal and pewter are alloys consisting primarily of tin with ca. 2 % Cu and 7 – 20 % Sb that are used in the manufacture of vases, lamps, candlesticks, tea and coffee services, etc. The antimony increases the hardness of the metal and permits a highly polished surface to be obtained.

Solders. Antimony is added to solders to increase the hardness of the tin – lead alloys. The Sb content is typically less than 1 % but may be as high as 13 % for certain applications such as electrical equipment, the end and side seams of cans, car radiators and other plumbing, and as a car-body filler for gaps in spot-welded seams.

Semiconductors. Increasing amounts of antimony are used as dopants in the manufacture of *n*-type semiconductors and III/V intermetallic semiconductor materials such as indium, aluminum, and gallium antimionide for the substrates of light-emitting diodes.

Antimony Trioxide. The uses of antimony trioxide can be divided into two broad categories: flame-retardant and non-flame-retardant. Antimony trioxide in combination with a halogen imparts flame-retardant properties to various materials. Ineffective on its own, the antimony must be intimately associated with the halogen, which is usually present as a chlorinated alkyd resin, a poly(vinyl chloride) resin, or a chlorinated plasticizer. A theory commonly used to explain this phenomenon recognizes that the primary mechanism concerns the generation of antimony trihalide and/or oxide halide. Antimony halides promote reactions that cause the formation of carbonaceous char rather than volatile gases. This char then acts as a heat shield that retards the breakdown of the plastics, thus preventing the release of flammable gases.

As an additive in plastics, antimony trioxide also acts as an opacifier. This is can be an desirable characteristic if colorant content is to be minimized. To minimize colorant requirements while retaining flame retardancy, the oxide particles should be 2 – 3 μm larger than the particles of standard pigments. Savings of up to 30 % in pigments can be achieved if the average grain size is increased from 1 to 3 μm. This explains the need for the fine control of the particle size during the final refining of the antimony trioxide. The market for antimony trioxide has expanded rapidly during since ca. 1970. *Flame-retardant applications* are as follows:

- Poly(vinyl chloride) for conveyor belts in mines, cable coatings, and coated fabrics for wall covering, cushion covers, etc.
- High-impact polystyrenes for television backs and domestic electrical appliances, and as housings for electrical equipment (including PCs)
- Polyethylene and polypropylene, primarily for wire sheathing and electrical conduits in buildings
- Polyamides and engineering plastics such as nylons for automotive uses, industrial equipment, and electrical moulded parts
- Unsaturated polyesters for applications such as building panels, automotive parts, and lifeboat hulls.

The major *non-flame-retardant* uses of antimony trioxide are as follows:

- In pigments, particularly in the manufacture of chromate pigments.
- As an opacifier for ceramic glazes and as a frit.
- In the refining of lead crystal glass and glass for television tubes. The oxide removes color and gas bubbles. Sodium antimonate is also used for these purposes.
- As a polymerization catalyst in the manufacture of polyester fibers.

Others. Antimony and antimony salts are used for a number of minor applications:

- Organic antimony compounds such as tartar emetic (potassium antimonyl tartrate) and fuadin are used in the treatment of certain tropical diseases such as bilharzia.
- In certain pesticides.
- Ammunition primers, flares, tracer shells, and fireworks (black powder).
- Vulcanization of red rubber compounds (SbS_5).
- Mordants
- As a lubricating agent in the manufacture of disk-brake pads and cutting disks.

14. Recycling

The main forms of *antimony scrap* are type metal, Babbitt metal, lead and tin waste, antimonial lead, and especially waste lead – acid batteries: the recycling of antimony is closely connected to lead recycling. The extent to which antimony is recycled has increased steadily over the last few decades, in proportion to the worldwide production of automobiles.

Antimony accounts for about 1.8 – 2 % of the total weight of an automobile battery, although the trend is towards using less. Today, waste batteries are separated mechanically into a plastics fraction, a metal fraction, and an oxide – sulfate sludge. The grid metal contains 87 – 88 % lead and 3 – 3.5 % antimony; the sludge, 70 – 76 % lead and 0.5 – 1 % antimony. Most refineries process these materials separately from ore or concentrate. The waste grid metal can be smelted in rotating reverberatory or rotary kilns to yield antimony – lead alloy. The sludge is treated with reagents that bind sulfur, e.g., iron filings and soda, and smelted under reducing conditions to antimonial lead in rotating reverberatory furnaces, short rotating furnaces, or in some cases rotating tube furnaces. The antimonial lead produced can be remelted together with lead containing a higher proportion of antimony to produce commercial alloy. Frequently, the antimony in the crude antimonial lead is converted by oxidation into an antimonial slag or skimmings, as in the refining of lead bullion. These oxidized products, essentially lead and antimony, are treated with fluxes and coal and smelted in short rotating or rotating reverberatory furnaces to yield lead containing a high proportion of antimony. Because battery alloys now contain less antimony, the proportion of antimony in recycled lead will be lower in the years to come [14].

Antimony used as antimony oxide is far more difficult to recycle and mostly ends up in household waste. A Japanese study found 7.6 ppm Sb in regular household waste. About 63 % of the antimony came from materials with a comparatively high antimony content: 30 % from curtains (2100 ppm Sb), 20 % from industrial textiles (250 ppm Sb), and another 10 % from bedding (150 ppm Sb) [156].

15. Economic Aspects

Antimony ores are mined in about 20 countries worldwide (see Table 1 and Chap. 4). In 2003, antimony mine production was estimated at about 81 600 t. Only three of the countries in which antimony is mined have mine production capacities that might influence the world market situation: China (86 %), Bolivia (2.8 %), and the Republic of South Africa (6.4 %).

The main capacities for the production of antimony metal and antimony oxide are also located in these countries. Further large production capacities can be found in Mexico, in the United States and in Australia. In 1991 the production capacities for antimony were estimated to be about 110 000 t Sb worldwide [18]. The antimony production in 1990 was 52 685 t Sb [157]. Because China's share of the world antimony production was about 40 % in 1990 [157] and has increased since then, these production figures are based on uncertain information and may differ considerably depending on the literature consulted.

Production from secondary raw materials still is of importance for the antimony market. The main source for antimony recycling are lead – acid storage batteries. In Europe about 30 % of the total antimony production originates from this source with a decreasing tendency [158]. In 1997 the smelter production of primary antimony in the United States was 26 700 t. At the same time the antimony production from secondary raw materials in the United States was 7550 t (22 %) [20].

Some important producers of antimony metal are as follows [158]:

Argentina	Calles y Chernitsky SA, Buenos Aires
Belgium	Campine SA, Brussels; NV Union Minieres SA (UM), Brussels
China	Dachang Ming Administration, Dachangzhen; Guang long Antimony Smelter, Hsikwangshan Antimony Works, Hsikwanshan Area; Hunan Non-Ferrous Metals Industry Corp, Changsha
Germany	Metaleurop GmbH, Hannover
France	Mines de la Lucette, Paris
Greece	Greek Metallurgical & Mining Co of Lavrion SA - Emmel, Lavrio
U.K.	MCP Wafer Technology Ltd, Milton Keynes
India	The Metal Powder Co Ltd, Thirumangalam
Japan	Dowa Mining Co Ltd, Tokyo; Nippon Rare Metal Inc, Yokohama; Nippon Seiko KK, Shimagawa-ku

Kyrgistan	Kadamdzhaisky Antimony Works, Oshsk
Netherlands	Billiton Whitemetaal BV, Naarden
Peru	Centromin Peru SA-Empresa Minera del Centro del Peru SA, Lima
Romania	Intreprindera Metalurgica de Metale Neferoase (Metallurgical Enterprise for Non-ferrous Metals), Copsa-Mica
Serbia	Trepca Works-Sour Rudarsko-Metalursko-Hemijski Kombinat Olova i Cinka, Titova; Zajaca Rudarsko Topionicarski Basen, Loznica
Slovakia	Vajskova Antimony Smelter, Vajskova
South Korea	Il Sung Antimony Co Ltd, Seoul
Turkey	Mutlu Akü ve Malzemeleri SAS, Istanbul; Ozdemir Antimuan Madenleri Ltd Sti, Istanbul
U.S.A.	Metalspecialties Inc, Fairfield; Ney Smelting & Refining, Brooklyn

Some important producers of antimony oxide are listed in the following:

Argentina	Calles y Chernitsky SA, Buenos Aires
Belgium	Campine SA, Brussels
Bolivia	Enaf-Empresa Metalurgica Vinto, Oruro
China	Guang Long Antimony Smelter
France	Mines de Lucetta, Paris
Italy	Ginatta SpA, Turin
Japan	Mitsui Mining & Smelting Co Ltd, Tokyo
Russia	Novosibirsk Rare Metal Works, Novosibirsk
Serbia	Zajaca Rudarsko Topinicarski Basen, Loznica
South Africa	Antimony Products (Pty) Ltd, Johannesburg
U.S.A	Amspec Chemical Corp, Gloucester City Asarco Inc, New York Ney Smelting & Refining, Brooklyn

Figure 9. Prices for antimony metal [159]

Figure 9 shows the price ranges for antimony from 1993 to 1996. The price has undergone large variations, especially in 1994. The dramatic increase of the antimony price in 1994 from 1700 $/t in January to 5900 $/t in November was caused by difficulties in the supply from China, the states of the former Soviet Union, and Bolivia. Again China's role was the main factor influencing the antimony market. Shortly after the price peak in 1994/95 the antimony price again reached an average value of about 2000 $/t. Antimony production in China is expected to decrease by up to 40 % in 1997/98 due to the high production costs of 2500 to 2800 $/t Sb. The strong dependency of the antimony price on China has led to plans for the reopening of older antimony mines (e.g., Thomson Falls). In addition, a new antimony trioxide plant will be opened in Canada in 1998. New sources might result in a greater degree of stability in the antimony industry worldwide [18, 20, 160, 161].

Future growth and demand for antimony will continue to depend on trends in consumption of antimony trioxide in flame retardants, which account for 45 % of the world antimony demand. Other growth areas are the use of antimony trioxide in polymerization catalysts for PET production and of sodium antimonate as decolorizer in glass for cathode ray tubes [162].

16. Toxicology

Antimony, which is considered a nonessential element, is comparable in its toxicological behavior to arsenic and bismuth [163]. In analogy to arsenic, trivalent antimony compounds generally are more toxic than the pentavalent compounds [164]. Poisoning with antimony and its compounds can result from acute and chronic exposure, especially from exposure to airborne particles in the workplace; to a minor extent, exposure occurs through treatment of tropical diseases with antimony compounds.

Toxicokinetics. Most antimony compounds, mainly those with poor water solubility, are absorbed only slowly from the gastrointestinal tract. Trivalent compounds especially tend to accumulate in the human body, because they are excreted very slowly via urine and feces [164]. Antimony and its compounds react readily with mercapto groups in various cellular constituents, especially in enzymes, blocking their activity. After acute and chronic intoxications, the highest levels of antimony were found in lungs, liver and kidneys [165].

Acute Toxicity. Acute oral poisoning by antimony compounds after ingestion of contaminated drinks was observed in 150 children; the symptoms were nausea, diarrhea, and vomiting

[166]. Acute intoxications with antimony trioxide, Sb_2O_3, lead to vomiting, diarrhea and abdominal pains; in cases of subchronic and chronic intoxication symptoms such as nausea, cough, headache, as well as pains of the stomach and muscles were observed. Acute respiratory exposure of seven workers to 70 – 80 mg/m^3 of antimony trichloride, $SbCl_3$, resulted in irritation of the upper respiratory tract [167]; in five cases disturbances of the gastrointestinal function and loss of appetite were observed. Antimony pentachloride, $SbCl_5$, caused severe pulmonary edema in three cases, two of them being lethal [168]. Stibine, SbH_3, a highly toxic, relatively unstable gas with an unpleasant odor, causes symptoms of the central nervous and circulatory systems, such as nausea, vomiting, headache, slow breathing, weak pulse, hemolysis, hematuria, abdominal pain, and death [169, 170]. Stibine is generated if nascent hydrogen can react with antimony in acid, e.g., in lead – acid batteries, where antimony may be a component of the battery plates [171].

People who are exposed to antimony and its compounds often show transient pustular skin eruptions [172]. These "antimony spots" mainly occur in those regions of the skin that are exposed to heat and sweat. In another case, three employees exposed to antimony metal dust and antimony trioxide fumes in a melting process developed a generalized eruption of follicular papules and pustules [173].

Antimony trifluoride and pentafluoride are highly toxic and irritant to the skin; they cause eczematous eruptions and inflammation of mucous membranes of nose and throat.

Chronic Toxicity. Chronic poisoning after oral ingestion of antimony compounds has been observed in many cases of clinical treatment with antimony compounds. These chronic intoxications resulted in nausea and vomiting [174]; liver damage, with increased plasma values of aspartate-aminotransferase and alanine-aminotransferase [175]; changes in the electrocardiogram, indicating a cardiotoxic effect of these compounds [176]; and even sudden death [177].

Most cases of chronic respiratory intoxications result from exposure to airborne particles in the workplace. In a study involving 78 workers in antimony smelters, symptoms such as soreness, nosebleeds, rhinitis, pharyngitis, pneumonitis, and tracheitis could be observed after exposure times of up to five months, the air containing antimony trioxide, Sb_2O_3, in a concentration of 4.7 – 11.8 mg/m^3 [172]. Exposure to Sb_2O_3, which is used in the glass-producing industry as a refining agent and glass colorant, leads to significantly increased levels in the urine of 1.5 to 15.7 µg/L (median: 5.0 µg/L). Due to the fast renal excretion of antimony, its determination in urine is useful for biological monitoring [178]. Long-term exposures often result in lung X-rays that are similar to those seen in pneumoconiosis [179, 180]. Workers who had been exposed to Sb_2O_3 for up to 28 years had pneumoconiosis (21 %) and symptoms of emphysema (42 %) [181]. Brieger et al. [182] extensively examined 125 workers who had inhaled antimony trisulfide, Sb_2S_3, in air at concentrations of 0.6 – 5.5 mg/m^3 for 8 – 24 months. An increased morbidity and mortality were observed among these workers. Changes in the electrocardiogram were seen in 37 cases out of 75. In addition, a significantly higher incidence (6 %) of peptic ulcers occurred within the group of workers exposed to antimony compared to the incidence within the total plant population (1.5 %). During the period of this study, six workmen died suddenly, and two others died from chronic heart diseases. After extensive exposure to antimony fumes, workers showed gastrointestinal symptoms, such as diarrhea, vomiting, and abdominal convulsions [172].

Mutagenicity, Carcinogenicity. Antimony has been demonstrated to be mutagenic in bacteria and phages, and to induce chromosomal aberrations and abnormal cell divisions in animal and plant cells [183]. Based on the data of animal experiments, antimony trioxide is a suspected carcinogen in humans [184]. There are limited epidemiologic data concerning a possible carcinogenicity of antimony compounds in humans [185, 186].

Toxicological Data.

Antimony, Sb, MAK 0.5 mg/m^3 (measured as *einatembarer Staubanteil*, inhalable fraction of dust) [184]; limit value for drinking water 0.01 mg Sb/L [187]; LDLo 100 mg/kg (rat, intraperit.) [188].

Antimony hydride, stibine, SbH_3, MAK 0.1 ppm (0.5 mg/m^3), LCLo 92 ppm (guinea pig, inhalation, 1 h) [189].

Antimony trifluoride, SbF_3, TLV 0.5 mg/m^3 (as Sb), LDLo 100 mg/kg (guinea pig, oral) [190].

Antimony trichloride, $SbCl_3$, TLV 0.5 mg/m^3 (as Sb), TDLo 73 mg/m^3 (human, inhalation) [167].

Antimony pentachloride, $SbCl_5$, TLV 0.5 mg/m^3 (as Sb), LD_{50} 1115 mg/kg (rat, oral) [191], causes mutation in *Bacillus subtilis* at 30 µL/disk [192].

Antimony trioxide, Sb_2O_3, carcinogenic potential suspected for humans, TLV 0.5 mg/m^3 (as Sb), TCLo 4.2 mg/m^3 during 52 weeks, carcinogenic (rat, inhalation) [193].

Antimony pentoxide, Sb_2O_5, LDLo 4000 mg/kg (rat, intraperit.) [188].

Antimony trisulfide, Sb_2S_3, TLV 0.5 mg/m^3 (as Sb), TCLo 580 µg/m^3 during 35 weeks (humans, inhalation) [182], LDLo 1000 mg/kg (rat, intraperit.) [188].

Antimony pentasulfide, Sb_2S_5, TLV 0.5 mg/m^3 (as Sb), LD_{50} 1500 mg/kg (rat, intraperit.) [188].

1. Introduction

The significant advances in antimycotic chemotherapy in the last decades are mainly due to the introduction of new, potent, and broadly active antimycotics to the market. The substances can be classified according to their mode of application into topical and systemic antimycotics. Topical antimycotics are applied to the skin, mucous membranes, and intravaginally in order to treat superficial mycoses locally. Peroral therapy and prophylaxis of intraluminal colonializations or infections of the gastrointestinal tract, e.g., with drops, syrups, or lozenges containing antimycotics that are not absorbed or are absorbed to an extremely small extent from the gastrointestinal tract (no or extremely low bioavailability) must also be regarded as topical therapy. Systemic antimycotics are applied parenterally and/or orally and show moderate to good bioavailability.

At present, numerous drugs for the topical treatment of superficial mycoses such as cutaneous and mucocutaneous infections are available, but there are only a limited number of drugs for the treatment of systemic mycoses. Additionally, resistance problems are arising, especially in the antimycotic chemotherapy of systemic mycoses, so that the medical need for new substances for this indication is great. Several "historical" compounds that show a relatively unselective antifungal activity, such as dyes, organic acids, mercury salts, and quaternary ammonium compounds, are sometimes still used in the treatment of superficial mycoses. Their therapeutic efficacy, tolerance, and patient acceptance are rated as low nowadays, and these substances are of decreasing relevance as much more selective antimycotics are available.

Modern antimycotics are expected to be effective in vitro, in animal models, and in infected humans and animals against one or more of the following classes of pathogenic fungi: dermatophytes (e.g., *Trichophyton* and *Microsporum* species, *Epidermophyton floccosum*), yeasts (e.g., *Candida* and *Torulopsis* species, *Cryptococcus neoformans*), moulds (e.g., *Aspergillus fumigatus* and other *Aspergillus* species, *Fusarium* species, zygomycetes such as *Mucor, Rhizopas,* and *Absidia* species), and dimorphic (biphasic) fungi, which can express a yeast phase, which is mostly the pathogenic form in the infected host, and a mould phase, which is mostly the infective, saprophytic form in nature, e.g., in soils [1].

In addition to the very common superficial mycoses of the skin and mucous membranes, yeasts, moulds, and dimorphic fungi can also induce serious, life-threatening generalized opportunistic infections, especially in immunocompromised hosts. As the number of patients at high risk of systemic mycoses (e.g., patients after transplantations, under aggressive antineoplastic chemotherapy or in intensive care, AIDS patients) is increasing steadily, these infections are much more common nowadays [1]. Dermatophytes solely cause infections of the skin, hair, and nails, and are unable to induce systemic, generalized mycoses, even in immunocompromised hosts.

The in vitro antimycotic activity of the substances is assessed by the determination of MIC values (minimal inhibitory concentrations). This is the lowest concentration of a substance that inhibits the growth of a fungal isolate in vitro. The MICs of antimycotics can vary considerably – up to as much as several decades – depending on culture conditions such as medium composition, incubation temperature, inoculum size and preparation method. Therefore, a high degree of standardization must be maintained to obtain comparable results. Furthermore, there is often only a poor or no in vitro/in vivo correlation of MIC values with the clinical outcome.

Some antimycotics, including azole agents, also show a moderate to mostly low in vitro antibacterial activity which does not seem to be relevant for the clinical situation during therapy. Therefore, these minor antibacterial properties of the substances are not discussed in this chapter. Many formulations, especially of topically applicable antimycotics, contain other compounds such as urea, antibiotics, and steroids. These combinations are not extensively discussed here.

2. Azole Antimycotics

Azoles with antimycotic properties can be devided into imidazole and triazole derivatives. Both groups have the same mechanism of antifungal action. Imidazole derivatives with antimycotic activity were first synthesized at Bayer and Janssen and described in 1968/1969. Serval important commercial products have been developed for human and veterinary medicine and plant protection [2].

Low doses of azole antimycotics produce morphological changes in sensitive fungi. These are reflected in changes in the cell volume and plasma membrane [3] and are probably due to the interaction of the azoles with ergosterol biosynthesis [4–7]. Biochemically, azoles specifically inhibit fungal ergosterol biosynthesis by interference with fungal specific isoenzymes of the cytochrome P450-dependent 14α-demethylation of lanosterol or 24-methylenedihydrolanosterol, which is a key step in the biosynthesis of ergosterol. The accumulation of membrane-disturbing 14α-methylsterols seems to be the origin of the antifungal properties of azole compounds, as known from in vitro studies [8]. Ergosterol is an essential constituent of the fungal plasma membrane, helping to maintain the integrity of the cell membrane which has a barrier function. Ergosterol deficiency leads to loss of essential cytoplasmatic constituents through the plasma membrane, and results in cessation of growth and even death of the fungus. In all studies, an accumulation of sterols with a methyl group on C14, which are unsuitable as membrane components, was observed [9], [10]. At higher doses, azoles also interfere with synthesis of fatty acids and triglyceride [4]. The weak antibacterial activity of these substances seems to be based on another mechanism. However, MIC values of azole antimycotics strongly depend on the test method and are mostly of limited use in predicting clinical efficacy.

2.1. Azole Antimycotics for Systemic Treatment

2.1.1. Fluconazole

Fluconazole [*86386-73-4*], α-(2,4-difluorophenyl)-α-(1*H*-1,2,4-triazol-1-ylmethyl)-1*H*-1,2,4-triazole-1-ethanol, $C_{13}H_{12}F_2N_6O$, M_r 306.27, *mp* 138 – 140 °C, crystals from ethyl acetate/hexane.

Synonym(s). UK 49858.

Solubility. Soluble in water.

Stability. The pure solid form is stable under normal storage conditions.

Description. The triazole antimycotic fluconazole was first synthesized at Pfizer Pharmaceuticals [11], [12].

Formulations. Capsules à 0.05, 0.1, 0.15, and 0.2 g. Suspensions (0.5 and 1 %) for oral application. Infusion bottles à 0.1, 0.2, and 0.4 g.

Trade Names. Biozolene (Bioindustria), Diflucan (Mason, Pfizer, Roerig), Dimycon (Alkaloid), Elazor (Sigma-Tau), Flavizol (Gador), Fungata (Mack), Mutum (Raffo), Triflucan (Pfizer).

Antimycotic Properties. Fluconazole is a broad spectrum triazole antimycotic with good in vitro and in vivo activity against pathogenic *Candida* species (apart from *Candida krusei*, which is a primary resistant *Candida* species), *Cryptococcus neoformans*, and dermatophytes [13]. *Aspergillus* species mostly show primary resistance towards fluconazole. Secondary resistance development can be observed after prolonged or repeated therapy of *Candida*-associated mycoses, especially in AIDS patients. In vitro susceptibilities of yeasts against fluconazole are reported in Table 1 [14].

Table 1. MIC values for fluoconazole

Fungus	No. isolates tested	MIC range, µg/mL
Candida albicans	443	0.125 – > 80
Candida kefyr	22	32 – 64
Candida lusitaniae	28	0.25 – 32
Candida parapsilosis	68	0.5 – 4
Candida tropicalis	88	0.5 – > 64
Trichosporon beigelii	15	1 – 64

Pharmacokinetics. The bioavailability after oral application ranges around 90 % [15]. The plasma concentrations and AUC (Area Under the Curve) are dose-proportional in the dose range of 50 – 400 mg/d [15]. After a single oral dose of 100 mg, a plasma concentration of 1.7 µg/L is achieved (6.7 µg/L after 400 mg) [16]. A steady state is mostly achieved after a therapy duration of 6 – 10 d. The serum protein binding of fluconazole is 12 % [17], and the plasma half-life 25 h. In *Cryptococcus neoformans* meningitis in AIDS patients, the liquor concentration was 80 % of the plasma concentration [18]. In vaginal secretions, the concentration of fluconazole was similar to the plasma concentration [19]; 60 – 75 % of the substance is eliminated by the kidneys in unmetabolized form. The elimination half-life is between 22 and 37 h [17].

Indications. Vaginal candidiasis [20] and systemic and mucocutaneous candidiasis [21–24]. In *Cryptococcus neoformans* meningitis the substance is mostly used in combination with amphotericin B and flucytosine [25]. Prophylaxis and preemptive therapy in AIDS patients, patients with leukemia, and patients with bone marrow transplants [26], [27].

Side Effects. Fluconazole is well tolerated.

CNS. Vertigo: 3.7 %, headache: 1.9 %.

GIT. Stomachache: 1.7 %, vomiting: 1.7 %, diarrhoea: 1.5 %.

Liver. Rise in transaminases (> 8 % of normal level): 1 %.

Skin. Exanthema: 1.8 %.

A Stevens – Johnson syndrome was observed after fluconazole therapy in an AIDS patient.

2.1.2. Itraconazole

Itraconazole [*84625-61-6*], 4-[4-[4-[4-[[2,4-Dichlorophenyl)-2-(1*H*-1,2,4-triazol-1-ylmethyl)-1,3-dioxolan-4-yl]-methoxy]phenyl]-1-piperazinyl]phenyl]-2,4-dihydro-2-(1-methylpropyl)-3*H*-1,2,4-triazol-3-one, $C_{35}H_{38}Cl_2N_8O_4$, M_r 705.64, *mp* 166.2 °C, crystals from toluene.

Synonym(s). R 51211.

Solubility. Itraconazole is a lipophilic substance which is practically insoluble in water and dilute acidic solutions. Partition coefficient in *n*-octanol/aqueous buffer of pH 8.1: 5.66.

Stability. The pure solid compund is stable under normal storage conditions.

Synthesis. Itraconazole is synthesized as follows [28], [29] (see top of next page):

Description. The triazole antimycotic itraconazole was first synthesized at Janssen Pharmaceuticals [30], [31].

Formulations. Capsules à 0.1 g.

Trade Names. Itrizole (Cilag), Sempera (Janssen), Siros (Cilag), Sporanox (Edward Keller, Janssen), Triasporin (Lifepharma).

Antimycotic Properties. Itraconazole is a broad-spectrum triazole antimycotic with good in vitro and in vivo activity against pathogenic dermatophytes, moulds (including *Aspergillus* species), *Candida* species, and dimorphic fungi such as *Blastomyces dermatitidis, Coccidioides immitis, Histoplasma capsulatum, Cryptococcus neoformans,* and *Sporothrix schenckii* [32–40]. MIC values of itraconazole are given in Table 2 [14].

Table 2. MIC values for itraconazole

Fungus	No. isolates tested	MIC range, µg/mL
Aspergillus fumigatus	96	0.001 – 10
Candida albicans	1605	0.063 – 128
Candida (Torulopsis) glabrata	4	2 – 128
Candida krusei	15	0.125 – 0.5
Candida lusitaniae	15	≤ 0.03 – 0.25
Candida parapsilosis	46	0.063 – > 128
Candida tropicalis	50	0.13 – > 128
Cryptococcus neoformans	118	0.001 – 0.5
Epidermophyton floccosum	5	0.063
Fusarium species	44	8 – > 32
Histoplasma capsulatum	10	0.063
Malassezia furfur	35	0.001 – 1
Microsporum species	10	0.063 – 0.25
Sporothrix schenckii	33	0.001 – 4
Trichophyton species	15	0.063 – 64
Trichosporon beigelii	15	≤ 0.03 – 0.25

Pharmacokinetics. The substance has a bioavailability after oral application of 40 % if taken on an empty stomach to 55 % if taken simultaneously with food [41]. The absorption of itraconazole after oral application is slow; peak plasma concentrations are reached 3 – 6 h after intake [41], [42]. Plasma concentrations are low, and a peak plasma concentration of 0.1 µg/L was observed after a single oral dose of 100 mg [42]. The serum protein binding of itraconazole is high; more than 99 % of the substance is bound to plasma proteins, mostly to albumin. The substance shows good tissue penetration, especially into the skin and nails [41]. Itraconazole is extensively metabolized in the liver, and more than 30 metabolites have been identified so far [43]. The elimination of the substance mostly occurs by the biliary-fecal route and renally in a metabolized form [44]. The elimination half-life ranges between 15 and 42 h, depending on the applied dose [41].

Indications. Therapy of dermatophytoses and onychomycoses [45–47] with a dosing regimen of 100 to 200 mg per day. Vaginal candidosis with 200 mg/d for 3 days [48]. Therapy of systemic infections such as candidosis and aspergillosis including disseminated infections, blastomycosis, coccidioidomycosis, histoplasmosis, and cryptococcosis with a dosing regimen of 100 to 400 (or up to 600) mg/d [49–51].

Especially in aspergillosis, an early onset of therapy is important for the clinical outcome.

Side Effects. Itraconazole is generally well tolerated.

CNS. Vertigo and headache: 10 %.

GIT. Stomachache, vomiting, and diarrhoea were observed.

Liver. Rise in transaminases and other reversible liver affections: 7 %.

Metabolism. Hypokaliemia and rise in serum triglycerides [52], [53].

2.1.3. Ketoconazole

Ketoconazole [*65277-42-1*], *cis*-1-acetyl-4-[4-[[2-(2,4-dichlorophenyl)-2-(1*H*-imidazol-1-ylmethyl)-1,3-dioxolan-4-yl]methoxy]phenyl]-piperazine, $C_{26}H_{28}Cl_2N_4O_4$, M_r 531.4, *mp* 146 °C, colorless crystals.

Synonym(s). R 41400.

Solubility. Ketoconazole is soluble in methanol, ethanol, and chloroform; slightly soluble in dilute acids; and barely soluble in water.

Stability. The pure solid compund is stable under normal storage conditions.

Synthesis. The synthesis of ketoconazole begins with the ketalization of 2,4-dichloroacetophenone (**1**) with glycerol. The intermediate (**2**) is not isolated but treated with

bromine to form the bromide (**3**). The benzoxylation of (**3**) gives (**4**) in the form of a *cis – trans* mixture. The *cis* form can be separated by crystallization. The reaction of (**4**) with imidazole in dimethylacetamide gives (**5**), which is then hydrolyzed to (**6**), which in turn is converted with methanesulfonyl chloride into the sulfonate (**7**). The reaction of (**7**) with the sodium salt of *N*-acetyl-*N*-*p*-hydroxyphenylpiperazine in DMSO gives ketoconazole.

Description. The imidazole antimycotic ketoconazole was first synthesized at Janssen Pharmaceuticals [54–58].

Formulations. Tablets à 0.2 g; 2 % solutions, ointments, and cream preparations.

Trade Names. Candoral (Aché), Cetonax (Cilag), Fitonal (Disprovent), Fungarest (Janssen), Fungicil (Labinca), Fungo-Hubber (Hubber), Fungoral (Ilsan, Janssen, Leo), Ketazol (Exa), Ketoderm (Janssen), Ketoisdin (Isdin), Ketonan (IMA), Ketoral (Bilim), Micoral (Cassara), Micotek (Kressfor), Micoticum (Vita), Nizoral (Abic, Edward Keller, Janssen), Nizshampoo (Janssen), Oromycosal (Alkaloid), Oronazol (Krka), Panfungol (Esteve), Rofenid (Rhône-Poulenc), Terzolin (Janssen).

Antimycotic Properties. Ketoconazole shows a good efficacy against dermatophytes, dimorphic fungi (*Blastomyces dermatitidis, Coccidioides immitis, Histoplasma capsulatum*), and pathogenic *Candida* species [59], [60]. The activity against hyphomycetes and *Cryptococcus neoformans* is limited. MIC values of ketoconazole are summarized in Table 3. The in vitro activity of ketoconazole, like that of the other azoles, is strongly dependent on the test method used.

Table 3. MIC values for ketoconazole

Fungus	MIC range, µg/mL
Dermatophytes	0.04 – 10
Candida species	0.04 – 40
Cryptococcus neoformans	0.08 – 5
Aspergillus species	1.25 – 40
Dimorphic fungi	0.04 – 5
Chromomycetes	0.04 – 20

Pharmacokinetics. After oral administration, ketaconazole shows a variable degree of absorption of up to 70 %. The degree of absorption depends on the pH of the gastric fluid [61], [62]. Antacids and H_2-antagonists reduce

the absorption of the drug. Peak serum concentrations are reached 2 – 4 h after administration and are between 2.0 and 3,5 µg/mL for a dose of 200 mg (3 mg/kg), and between 3.5 and 7.0 µg/mL for a 400 mg dose. Serum concentrations of 10 – 20 µg/mL can be reached after administration of a single dose of 1200 mg [63]. The substance shows a binding potency to plasma proteins and erythrocytes of 99 % [61]. After vaginal application, 1 % of the substance is absorbed; after cutaneous application, no absorption could be measured [64]. Ketoconazole penetrates well into the stratum corneum of the skin and vaginal secretions [61]. The concentration of ketoconazole in urine is low, with less than 1 µg/mL after a daily dose of 400 mg. The drug diffuses only slowly into the cerebrospinal fluid, where it reaches about 5 % of the serum concentration. The elimination half-life ranges from 4 to 9 h. The substance is mainly eliminated by the biliary – fecal route in a metabolized, inactive form.

Indications. Systemic therapy of dermatomycoses, blastomycosis, coccidioidomycosis, and histoplasmosis. Because of the side effects of ketoconazole, the newer azoles such as fluconazole and itraconazole should be considered instead of ketoconazole for systemic treatment. Ketoconazole is especially indicated in topical therapy of dermatomycoses, pityriasis versicolor, seborrheoic dermatitis, and dandruff.

Side Effects. After oral administraition of ketaconazole, side effects are seen at up to 10 % (400 mg/d) to > 50 % (800 mg/d) [65].

CNS. Vertigo, dizziness, and headache.

GIT. Somachache, loss of appetite, vomiting, and diarrhoea.

Liver. Rise in transaminases and other liver affections which are mostly reversible, although fulminant hepatitis was observed in 1 in 10 000 cases.

Vessels. Angioedema. Further, skin reactions, insomnia, and lethargy can be observed. Gynaecomastia, oligospermia, loss of libido, and alopecia, which may occur, are due to an inhibition of testosterone and cortisol biosynthesis [66–69]. Daily doses of higher than 400 mg reduce the testosterone serum concentration.

2.1.4. Miconazole

Miconazole [*22916-47-8*], 1-[2-(2,4-dichlorophenyl)-2-[(2,4-dichlorophenyl)methoxy]ethyl]-1*H*-imidazole, $C_{18}H_{14}Cl_4N_2O$, M_r 415.92.

Miconazole nitrate, [*22832-87-7*], $C_{18}H_{15}Cl_4N_3O_4$, M_r 479.15, *mp* 184 – 185 °C, colorless crystals.

Synonym(s). R 18134; R 14889 (mononitrate).

Solubility. Miconazole is barely soluble in water (0.3 mg/mL) and slightly soluble to soluble in the many organic solvents and dilute inorganic acids.

Stability. The pure solid compound is stable under normal storage conditions.

Synthesis. The synthesis [70], [71] begins with 2,4-dichloroacetophenone, which is first brominated to form the phenacyl bromide and then treated with imidazole to form the phenacylimidazole. Reduction with sodium borohydride and reaction of the resulting alcohol

with 2,4-dichlorobenzyl chloride yields miconazole.

Description. The imidazole antimycotic miconazole was first synthesized at Janssen Pharmaceuticals [72], [73].

Formulations. Ampulles à 0.2 g; lozenges à 0.25 g; 2 % solutions, lotions, powders, gels, ointments, and cream preparations; vaginal ovula.

Trade Names (Miconazole). Andergin (Pierell), Brentan (Janssen), Daktar (Janssen), Daktarin (Abic, Edward Keller, Janssen), Dumicoat (Dumex), Femeron (Janssen), Micofim (Elofar), Micotar (Dermapharm), Micotef (LPB), Monistat (Cilag, Ethnor, Janssen), Monistat I.V. (Janssen), Vodol (Searle).

Trade Names (Miconazole Nitrate). Aflorix (Gerardo Ramon), Albistat (Cilag), Aloid (Janssen), Andergin (Pierrel), Anotit (Janssen), Brenazol (DuraScan), Brentan (Janssen), Britane (Janssen), Canofite (Janssen), Conoderm (C-Vet), Conofite (Janssen, Pitman-Moore), Daktar (Janssen), Daktarin (Abic, Janssen), Decomyc (Merck), Deralbine (Andromaco), Dermacure (Janssen), Dermonistat (Ortho), Epi-Monistat (Cilag, Janssen), Florid (Janssen, Mochida), Fungiderm (Janssen), Funginazol (Morgens), Fungisdin (Esteve, Janssen), Fungucit (Iltas), Fungur (Salutas), Gyno-Daktar (Janssen), Gyno-Daktarin (Edward Keller, Janssen, Johnson & Johnson), Gyno-Monistat (Cilag, Janssen), Ipec (Byk-Gulden), Micatin (McNeil, Ortho), Micoderm (Italsuisse), Micogel (Cipla), Micogyn (Elofar), Miconal (Ecobi), Micotef (LPB), Monistat (Cilag, Janssen, Ortho), Monostat 7 (Ortho), Mykotral (Chephasaar), Prilagin (Gambar), Surolan (Janssen), Vodol (Searle).

Antimycotic Properties. Miconazole is a broad-spectrum imidazole antimycotic that generally shows activity against pathogenic dermatophytes (*Epidermophyton floccosum; Trichophyton* and *Microsporum* species), *Candida* species, moulds including *Aspergillus* species, and pathogenic dimorphic fungi [74–78]. MIC values are summarized in Table 4.

Table 4. MIC values for miconazole

Fungus	No. isolates tested	MIC range µg/mL
Aspergillus fumigatus	74	0.5 – 64
Blastomyces dermatitidis	57	0.001 – 2
Candida albicans	1815	0.016 – 100
Candida (Torulopsis) glabrata	224	0.016 – 64
Candida kefyr	33	0.016 – 4
Candida krusei	40	< 0.063 – 6.25
Candida lusitaniae	7	0.18 – 6.3
Candida parapsilosis	54	0.016 – 32
Candida tropicalis	172	0.016 – 33
Coccidioides immitis	99	0.063 – 6
Cryptococcus neoformans	69	0.063 – 25
Epidermophyton floccosum	19	0.06
Histoplasma capsulatum	48	0.05 – 2
Malassezia furfur	44	0.2 – 50
Microsporum canis	18	0.1 – 4
Pseudoallescheria boydii	42	< 0.016 – 4
Sporothrix schenckii	65	0.5 – 16
Trichophyton mentagrophytes	28	0.1 – 4
Trichophyton rubrum	63	0.001 – 32

Phamacokinetics. Miconazole is incompletely absorbed after oral application with an average bioavailability of 27 % [79]. The active drug is dissolved in Cremophor EL for intravenous administration. After intravenous administration of a single dose of 200 mg, a peak plasma concentration of 1.6 mg/L was observed. Infusion of 500 mg of miconazole briefly produces serum concentrations of 2 – 9 µg/mL, which, however, rapidly fall to under 0.2 µg/mL. Miconazole is barely absorbed after cutaneous and/or mucocutaneous application. The substance shows a plasma protein binding of 90 % and poor penetration into the liquor cerebrospinalis and other body fluids. Miconazole is extensively metabolized in the liver. The substance is eliminated predominantly by the biliary – fecal route as inactive metabolites. Elimination occurs in phases with a terminal elimination half-life of 24 h [79].

Indications. Especially topical therapy of skin infections caused by dermatophytes and yeasts, and mucocutaneous infections including *Candida* vulvovaginitis. Systemic, intravenous therapy especially of infections caused by *Pseudoallescheria boydii* (dosage up to 1.2 g 3 × per day) [80]. For treatment of other generalized my-

coses, mostly the newer, more effective, and less toxic azole antimycotics for systemic use, such as fluconazole and itraconazole, are indicated.

Side Effects. Multiple side effects have been observed after intravenous infusion of miconazole, which seem to be partly due to the formulation of the solvent, which contains the detergent Cremophor EL; mostly anaphylactic reactions, pruritus, dizziness, tachyarrhythmia, hyperaggregation of erythrocytes, anemia, thromocytosis, phlebitis, nausea, vomiting, hyperlipidemia, hyponatriemia, arthralgia, and flush [81].

2.2. Azole Antimycotics for Topical Treatment

2.2.1. Bifonazole

Bifonazole [*60628-96-8*], 1-([1,1'-biphenyl]-4-ylphenylmethyl)-1*H*-imidazole, $C_{22}H_{18}N_2$, M_r 310.4, *mp* 147 – 148 °C, colorless, odorless, tasteless crystals.

Synonym(s). Trifonazole, Bay h 4502.

Solubility. Bifonazole is soluble in glacial acetic acid (833 mg/mL), chloroform (344 mg/mL), benzene (38.2 mg/mL), methanol (36.5 mg/mL), ethanol (24.6 mg/mL), ethyl acetate (17.1 mg/mL), and acetonitrile (10.4 mg/mL). It is practically insoluble in water, but in Walpole's buffer, solubility is 3.75 mg/mL at pH 2.

Stability. Pure bifonazole is stable under normal storage conditions. In solution, the substance is stable under neutral or slightly alkaline conditions. It slowly decomposes in strongly alkaline or strongly acidic media. Bifonazole solutions are sensitive to light.

Synthesis. Bifonazole is synthesized as follows:

Description. The imidazole antimycotic bifonazole was first synthesized at Bayer Pharmaceuticals in 1974 [82–86].

Formulations. 1 % solutions, powders, gels, ointments, and cream preparations.

Trade Names. Amycor (Lipha), Azolmen (Menarini), Bifonazol (Bayropharm), Micofun (Incobra), Mycospor (Bayer, Kai Cheong), Mycosporin (Bayer).

Antimycotic Properties. Bifonazole is a broad-spectrum imidazole antimycotic with excellent in vitro activity against pathogenic dermatophytes, yeasts, moulds, and dimorphic fungi. MIC values of bifonazole are summarized in Table 5.

Table 5. MIC values for clotrimazole and bifonazole

Fungus	MIC range, µg/mL	
	clotrimazole	bifonazole
Dermatophytes	<0.01 – 2	0.01 – 1
Candida species	0.04 – 10	0.08 – 10
Cryptococcus neoformans	0.04 – 10	0.04 – 2.5
Pityrosporum species	2 – 4	0.5 – 1
Aspergillus species	0.1 – 1.25	0.5 – 1
Chromomycetes	0.04 – 2.5	<0.04 – 0.31
Dimorphic fungi	0.04 – 0.31	<0.04 – 0.08

Pharmacokinetics. Bifonazole is absorbed adequately after oral administration to humans and animals. The substance quickly induces ribosomal liver enzymes and is primarily metabolized to metabolites without antimycotic activity. Therefore, bifonazole can only be used as a topical antimycotic [87], [88]. The substance is minimally absorbed after topical application of 1 % formulations. Concentrations in blood serum remain below 5 ng/mL, even after long term treatment of a 200 cm^2 skin area. Concentrations in the stratum papillare of the skin reach 2 – 3 µg/g [88].

Indications. Topical treatment of mycoses of the skin induced or sustained by fungi such as dermatophytes, yeasts, and also chromomycetes.

Side Effects. Topical applications, including intravaginal application, are well tolerated. Skin irritations and allergic reactions are rarely observed and seem to be mainly due to the galenic formulation (e.g., fatty preparations on acute, inflammative lesions). Allergic reactions are rarely observed [89].

2.2.2. Butoconazole

Butoconazole [*64872-76-0*], (±)-1-[4-(4-chlorophenyl)-2-[(2,6-dichlorphenyl)thio]butyl]-1*H*-imidazole, $C_{19}H_{17}Cl_3N_2S$, M_r 411.78, *mp* 68 – 70.5 °C, crystals from cyclohexane.

Butoconazole nitrate [*64872-77-1*], $C_{19}H_{18}Cl_3N_2O_3S$, M_r 475.01, *mp* 162 – 163 °C, colorless blades from acetone/ethyl acetate.

Solubility. For further information, see [90].

Stability. The pure solid compound is stable under normal storage conditions.

Synthesis [91]:

Description. The imidazole antimycotic butoconazole was first synthesized at Syntex Pharmaceuticals [92].

Formulations. 2 % cream preparations.

Trade Names (Butoconazole Nitrate): Femcosyn (Protochemie), Femstat (Syntex), Gynomyk (Cassenne).

Antimycotic Properties. Broad-spectrum imidazole antimycotic with in vitro and in vivo activitiy against pathogenic yeasts, dermatophytes, moulds, and dimorphic fungi [93], [94].

Pharmacokinetics. After intravaginal application of 100 mg of butoconazole nitrate, 5 % of the dose was found in the urine and feces [95].

Indications. Butoconazole is generally indicated for therapy of vulvovaginal mycoses caused by *Candida* species and *Candida (Torulopsis) glabrata* [96], [97].

Side Effects. Local irritations such as itching and burning sensations and allergic reactions may occur in rare cases and are mainly due to the galenic formulation [98].

2.2.3. Clotrimazole

Clotrimazole [*23593-75-1*], 1-[(2-chlorophenyl)diphenylmethyl]-1*H*-imidazole, $C_{22}H_{17}ClN_2$, M_r 344.8, *mp* 143 – 144 °C, colorless, tasteless crystals.

Synonym(s). Chlortritylimidazole, Bay 5097, FB b 5097, PCPIM.

Solubility. Clotrimazole is readily soluble in methanol, chloroform, and DMF (all > 100 mg/mL); slightly soluble in acetone (50 mg/mL), ethyl acetate (45 mg/mL), ethanol (95 mg/mL), and PEG 400 (60 mg/mL); and practically insoluble in water (< 0.01 mg/mL).

Stability. Pure clotrimazole is stable under normal storage conditions. The stability of the solution is pH dependent. Above pH 7 the solution is stable. In acid solution, clotrimazole undergoes gradual hydrolysis to form 2-chlorophenylbisphenylmethanol and imidazole. The hydrolysis half-life at pH 1 is about 170 h in ethanol/water (1/1) at room temperature.

Synthesis. The synthesis of clotrimazole begins with 2-chlorobenzyl chloride, which is converted to benzotrichloride. Friedel – Crafts reaction with benzene followed by reaction with imidazole forms clotrimazole [99].

Description. The imidazole antimycotic clotrimazole was first synthesized at Bayer Pharmaceuticals in 1967 [100]. Ist antimycotic activity was first reported in 1969 [101], [102–104].

Formulations. Solutions, powders, gels, ointments, and cream preparations; lozenges and vaginal tablets.

Trade Names. Agisten (Agis), Akneclor (Spirig), Antifungol (Hexal), Antimicotico (Savoma), Antimyk Neu (Pfleger), Apocanda (Apogepha), Azutrimazol (Azuchemie), Canesten (Bayer, Bayropharm, Kai Cheong), Canifug (Wolf), Clazol (Ilsan), Clocim (Cimex), Clot-basan (Sagitta), Clotrifug (Wolff), Clotrimaderm (Taro), Clotrimix (Hosbon), clotri OPT (Optimed), Clotrizol (Jossa), Clozole (Jean-Marie), Contrafungin (PharmaGalen), Cutistad (Stada), Dignotrimazol (Dignos), Dolexalan (Wölfer), Durafungol (Durachemie), Empecid (Bayer, Yoshitomi), Eurosan (Mepha), Femcare (Schering-Plough), Fungiframan (Oftalmiso), Fungi-med (Permamed), Fungizid-ratiopharm (ratiopharm), Fungosten (Mulda), Fungotox (Mepha), Gilt (Lyssia), Gino-Canesten (Bayer), Gino-Clotrimix (Hosbon), Gino-Lotramina (Schering Corp.), Gromazol (Grossman), Gyne-Lotremin (Mason, Schering Corp., Schering-Plough), Jenamazol (Jenapharm), KadeFungin (Kade), Localicid (Dermapharm), Lotramina (Schering Corp.), Lotremin (Mason, Schering Corp.), Lotrimin (Schering Corp., Schering-Plough), Micomisan (Hosbon), Micoter (Cusi), Mono-Baycuten (Bayropharm), Mycelex (Bayer, Dome), Mycelex-7 (Bayer), Mycelex-G (Bayer, Dome), Myclo (Boehringer Ingelheim), Mycofug (Hermal), Myco-Hermal (Hermal, Jebsen), Mycoril (Remedica), Mycosporin (Bayer), Mycotrim (Lagap), Myko Crdes (Ichthyol), Mykofungin (Wyeth), Mykohaug C (Salutas), Ovis Neu (Aldenylchemie), Peckle (Hisamitsu), Pedisafe (Sagitta), Plimycol (Pliva), SD-Hermal (Hermal), Stiemazol (Stiefel), Tibatin (DAK), Tricosten (Farmion), Trimysten (Bellon), Uromykol (Hoyer).

Antimycotic Properties. Broad-spectrum imidazole antimycotic with good activity against yeasts, dermatophytes, moulds, and dimorphic fungi. MIC values of clotrimazole are summarized in Table 5.

Pharmacokinetics. Clotrimazole is absorbed adequately after oral administration to humans and animals. The substance quickly induces ribosomal liver enzymes and is primarily metabolized to metabolites without antimycotic activity. Therefore, clotrimazole can only be used as a topical antimycotic [105], [106]. The substance is minimally absorbed after the topical application of 1 % formulations. Concentrations in blood serum remain below 5 ng/mL, even after long-term treatment of a 200 cm^2 skin area. Concentrations in the stratum papillare of the skin reach 2 – 3 µg/g [106].

Indications. Topical treatment of mycoses of the skin induced or sustained by fungi such as dermatophytes, yeasts, and chromomycetes. In addition, clotrimazole is indicated for therapy of vulvovaginal mycoses caused by *Candida* species and *Candida (Torulopsis) glabrata.*

Side Effects. Topical applications, including intravaginal application, are well tolerated. Skin irritations and allergic reactions are rarely observed and seem to be mainly due to the galenic formulation (e.g. fatty preparations on acute, inflammative lesions). Allergic reactions are rarely observed [107].

2.2.4. Croconazole

Croconazole [*77175-51-0*], 1-[1-[2-(3-chlorobenzyloxy)phenyl]vinyl]imidazole, $C_{18}H_{15}ClN_2O$, M_r 310.78, *mp* 72 – 73 °C, white crystals.

Croconazole hydrochloride [*77174-66-4*], $C_{18}H_{16}Cl_2N_2O$, M_r 347.24, *mp* 148.5 – 150 °C, white crystals.

Synonym(s). Croconazole (free base); S 710674 (hydrochloride).

Solubility. Soluble in ethyl acetate.

Stability. The pure solid compound is stable under normal storage conditions.

Description. The imidazole antimycotic croconazole was first synthesized at Shionogi Pharmaceuticals [108], [109].

Formulations. 1 % creams and gel preparations.

Trade Names (Croconazole Hydrochloride). Pilzcin (Merz, Merz + Schoeller, Shionogi).

Antimycotic Properties. Broad-spectrum imidazole antimycotic with activity against almost all pathogenic fungi.

Pharmacokinetics. Croconazole is not absorbed after cutaneous application.

Indications. Topical treatment of mycoses of the skin induced or sustained by fungi such as dermatophytes and yeasts.

Side Effects. Local irritations and allergic reactions after topical treatment may occur in rare cases and are mainly due to the galenic formulation.

2.2.5. Econazole

Econazole [*27220-47-9*], 1-[2-[(4-chlorphenyl)-methoxy]-2-(2,4-dichlorophenyl)ethyl]-1*H*-imidazole, $C_{18}H_{15}Cl_3N_2O$, M_r 381.69, *mp* 86.8 °C, colorless crystals.

Econazole nitrate [*68797-31-9*], $C_{18}H_{16}Cl_3N_3O_4$, M_r 444.7, *mp* 164 – 165 °C, colorless crystals.

Synonym(s). R 14827 (mononitrate).

Solubility. Econazole is soluble in methanol, acetic acid, and PEG 400; less soluble in ethanol, acetone, chloroform, and butanol; and barely soluble in water, ether, cyclohexane, and hexane [110].

Stability. The solid substance is stable under usual storage conditions but should be stored in the dark.

Synthesis. The synthesis is almost the same as that of miconazole (see Section 2.1.4) [70], [71], [111], differing only in the last stage, in which the 1-[2,4-dichloro[β-hydroxy)phenethyl]imidazole intermediate is treated with 4-chlorobenzyl chloride.

Description. The imidazole antimycotic econazole was first synthesized at Janssen Pharmaceuticals [111] in 1969 [112], [113].

Formulations. 1 % solutions, powders, ointments, and cream preparations; vaginal ovula (150 mg).

Trade Names (Econazole). Pevalip (Janssen), Pevaryl (Cilag), Pevaryl Lipogel (Cilag, Janssen), Pevaryl lotion (Cilag), Pevaryl P.V. (Cilag).

Trade Names (Econazole Nitrate). Amicel (Salus), Chemionazolo (Brocchieri), Dermazol (CT), Dermazole (Lision Hong), Ecalin (JAKA-80), Ecodergin (Leben's), Eco Mi (Geymonat), Ecorex (Tosi), Ecostatin (Squibb, Westwood-Squibb), Ecotam (Alacan), Epi-Pevaryl (Cilag), Etramon (Johnson & Johnson), Fitonax (Cilag), Gyno-Pevaryl (Cilag, Edward Keller), Ifenec Zilliken), Micocert (Dexter), Micoespec (Centrum), Micofungal (Labopharma), Micogin (Crosara), Micogyn (Crosara), Micos (AGIPS), Micosten (Bergamon), Micostyl (Stiefel), Mitekol (Lek), Mykopevaryl (Cilag), Pargin (Gibipharma), Pevaryl (Cilag, Edward Keller, Smith Kline Beecham), Pevaryl P.V. (Edward Keller), Polycain (Taiho), Skilar (Bonomelli), Spectazole (Ortho).

Antimycotic Properties. Broad-spectrum imidazole antimycotic with activity against almost all species of pathogenic fungi [114], [115]. MIC values of econazole are summarized in Table 6 [14].

Table 6. MIC values for econazole

Fungus	No. isolates tested	MIC range µg/mL
Aspergillus fumigatus	24	0.15 – 25
Candida albicans	283	0.016 – 25
Candida (Torulopsis) glabrata	38	0.016 – 25
Candida kefyr	33	0.016 – 6.25
Candida krusei	34	0.125 – 12.5
Candida parapsilosis	32	0.016 – 25
Candida tropicalis	52	0.016 – 25
Malassezia furfur	19	0.0125 – 25

Pharmacokinetics. After vaginal application, 1 – 27 % of the applied dose was found in the urine [116], [117].

Indications. Topical treatment of mycoses of the skin induced or sustained by fungi such as dermatophytes and yeasts [118]. In addition, econazole is indicated for therapy of vulvovaginal mycoses caused by *Candida* species and *Candida (Torulopsis) glabrata* [119], [120].

Side Effects. Local irritations such as itching and burning sensations and allergic reactions may occur in rare cases after topical therapy and are mainly due to the galenic formulation [121].

2.2.6. Fenticonazole

Fenticonazole [*72479-26-6*], 1-[2-(2,4-dichlorophenyl)-2-[[4-(phenylthio)phenyl]-methoxy]ethyl]-1*H*-imidazole, $C_{24}H_{20}Cl_2N_2OS$, M_r 455.4.

Fenticonazole nitrate [*73151-29-8*], $C_{24}H_{21}Cl_2N_3O_4S$, M_r 518.63, *mp* 136 °C, odorless white crystalline powder.

Synonym(s). Rec 15/1476 (mononitrate).

Solubility. Solubility at 20 °C: water < 0.1 mg/mL, diethyl ether < 0.1 mg/mL, ethanol 30 mg/mL, methanol 100 mg/mL, chloroform 300 mg/mL, DMF 600 mg/mL [122].

Stability. The pure solid compund is stable under normal storage conditions.

Description. The imidazole antimycotic fenticonazole was first synthesized at Recordati Pharmaceuticals [123], [124].

Formulations. 2 % solutions, ointments, and cream formulations; vaginal ovula (600 mg).

Trade Names (Fenticonazole Nitrate). Falvin (Farmades), Fenizolan (Organon), Fentiderm (Zyma), Fentigyn (Novartis), Lomexin (Grünenthal, Recordati), Mycodermil (Vifor Fribourg).

Antimycotic Properties. Broad-spectrum imidazole antimycotic with activity against almost all species of pathogenic fungi.

Pharmacokinetics. After topical application, the substance is not absorbed.

Indications. Topical treatment of mycoses of the skin induced or sustained by fungi such as dermatophytes and yeasts [125], [126]. In addition, fenticonazole is indicated for therapy of vulvovaginal mycoses caused by *Candida* species and *Candida (Torulopsis) glabrata* [127].

Side Effects. Local irritations such as itching and burning sensations and allergic reactions may occur in rare cases and are mainly due to the galenic formulation.

2.2.7. Isoconazole

Isoconazole [*27523-40-6*], 1-[2-(2,4-dichlorophenyl)-2-[(2,6-dichlorophenyl)methoxy]ethyl]-1*H*-imidazole, $C_{18}H_{14}Cl_4N_2O$, M_r 416.1, white crystals.

Isoconazole nitrate [*24168-96-5*], $C_{18}H_{15}Cl_4N_3O_4$, M_r 479.1, *mp* 182 – 183 °C, colorless crystals.

Synonym(s). R 15454 (mononitrate).

Solubility. Isoconazole is soluble in methanol, acetic acid, and PEG 400; less soluble in ethanol, acetone, chloroform, and butanol; and barely soluble in water, diethyl ether, cyclohexane, and hexane.

Stability. The solid substance is stable under normal storage conditions.

Synthesis. The synthesis of isoconazole [128] differs from that of miconazole (see Section 2.1.4) only in the last stage, in which 1-[2,4-dichloro(β-hydroxy)phenethyl]imidazole is treated with 2,6-dichlorobenzyl chloride in hot benzene – DMF in the presence of sodium hydride.

Description. The imidazole antimycotic isoconazole was first synthesized at Janssen Pharmaceuticals [128–131].

Formulations. 1 % solutions, ointments, and cream formulations.

Trade Names (Isoconazole Nitrate). Fazol (Bellon), Gyno-Travogen (Jebsen, Schering), Icaden (Schering), Isogyn Ginecologico (Crosara), Mupaten (Schering-Plough), Travogen (Jebsen, Schering), Travogyn (Schering).

Antimicrobial Properties. Broad-spectrum azole antimycotic with activity against almost all species of pathogenic fungi [132], [133].

Pharmacokinetics. After topical application, isoconazole remains practically unabsorbed. Application in an ethanol/propyleneglycol vehicle increases penetration into the stratum corneum of the skin significantly [134].

Indications. Topical treatment of mycoses of the skin induced or sustained by fungi such as dermatophytes and yeasts. In addition, isoconazole is indicated for therapy of vulvovaginal mycoses causes by *Candida* species and *Candida (Torulopsis) glabrata* [135].

Side Effects. Local irritations such as itching and burning sensations and allergic reactions may occur in rare cases and are mainly due to the galenic formulation.

2.2.8. Omoconazole

Omoconazole [*74512-12-2*], (*Z*)-1-[2-[2-(4-chlorophenoxy)ethoxy]-2-(2,4-dichlorophenyl)-1-methylethenyl]-1*H*-imidazole, $C_{20}H_{17}C_{13}N_2O_2$, M_r 423.73, *mp* 89 – 90 °C, crystals from ethyl acetate/hexane (1/4).

Omoconazole nitrate [*83621-06-1*], $C_{20}H_{18}Cl_3N_3O_5$, M_r 485.96, *mp* 118 – 120 °C (Büchi) / 122.5 (Mettler), crystals from ethyl acetate/ethanol.

Synonym(s). CM 8282 (mononitrate).

Stability. The pure solid substance is stable under normal storage conditions.

Description. The imidazole antimycotic omoconazole was first synthesized at Siegfried Pharmaceuticals [136], [137]. Stereospecific synthesis [138].

Formulations. 1 % cream formulations.

Trade Names (Omoconazole Nitrate). Azameno (Kwizda, Wyeth), Fongamil (Biorga), Fongarex (Sanofi), Fongorex (Siegfried), Melur (Siegfried).

Antimycotic properties. Broad-spectrum imidazole antimycotic with activity against almost all pathogenic fungi [139].

Pharmacokinetics. After topical application, omoconazole is not absorbed.

Indications. Topical treatment of mycoses of the skin induced or sustained by fungi such as dermatophytes and yeasts.

Side Effects. Local irritations such as itching and burning sensations and allergic reactions may occur in rare cases and are mainly due to the galenic formulation.

2.2.9. Oxiconazole

Oxiconazole [*64211-45-6*], (*Z*)-1-(2,4-dichlorophenyl)-2-(1*H*-imidazol-1-yl)ethanone *O*-[(2,4-dichlorophenyl)methyl]oxime, $C_{18}H_{13}Cl_4N_3O$, M_r 429.92.

Oxiconazole nitrate [*64211-46-7*], $C_{18}H_{14}Cl_4N_4O_4$, M_r 492.15, *mp* 137 – 138 °C, crystals from ethanol.

Synonym(s). Ro 13-8996/000 (free base); Ro 13-8996/001, Sgd 301-76 (mononitrate).

Stability. The pure solid substance is stable under normal storage conditions.

Synthesis. Oxiconazole is synthesized as follows [140], [141]:

Description. The imidazole antimycotic oxiconazole was synthesized at Roche and Siegfried Pharmaceuticals [142], [143].

Formulations. 1 % solutions, powders, ointments, and cream formulations. Vaginal tablets (600 mg).

Trade Names (Oxiconazole Nitrate). Gyno-Myfungar (Klinge), Myfungar (Klinge, Siegfried, Wyeth), Oceral (Roche), Oxistat (Glaxo).

Antimycotic Properties. Broad-specktrum imidazole antimycotic with activity against almost all species of pathogenic fungi [144].

Pharmacokinetics. After local application, oxiconazole penetrates well into the stratum corneum of the skin and the hair follicle [145].

Indications. Topical treatment of mycoses of the skin induced or sustained by fungi such as dermatophytes and yeasts. In addition, oxiconazole is indicated for therapy of vulvovaginal mycoses caused by *Candida* species and *Candida (Torulopsis) glabrata* [146].

Side Effects. Local irritations such as itching and burning sensations, and allergic reactions may occur in rare cases and are mainly due to the galenic formulation.

2.2.10. Sertaconazole

Sertaconazole [*99592-32-2*], (±)-1-[2,4-dichloro-β-[(7-chlorobenzo[*b*]thien-3-yl)methoxy]phenethyl]imidazole, $C_{20}H_{15}Cl_3N_2OS$, M_r 437.78.

Sertaconazole nitrate [*99592-39-9*], $C_{20}H_{15}Cl_3N_3O_4S$, M_r 501.01, *mp* 158 – 160 °C, odorless, white crystalline powder.

Synonym(s). FI-7045 (free base); FI-7056 (mononitrate).

Solubility. Fairly soluble in ethanol (1.7 %), chloroform (1.5 %); slightly soluble in acetone (0.95 %); very slightly soluble in *n*-octanol (0.069 %). Practically insoluble in water (< 0.01 %).

Stability. The pure solid substance is stable under normal storage conditions.

Synthesis. The Synthesis is described in [147].

Description. See [148], [149].

Formulations. 1 % cream formulations, gels, and ointments. New formulations for the treatment of vaginal candidiasis and oral formulations for the prophylaxis and treatment of mucocutaneous buccopharyngeal candidiasis are being developed.

Trade Names (Sertaconazole Nitrate). Dermofix (Ferrer), Dermoseptic (Smith Kline Beecham), Zalain (Robert).

Antimycotic Properties. Sertaconazole is a rather new broad-spectrum imidazole antimycotic with activity against almost all species of pathogenic fungi. It also has excellent activity against pathogenic yeasts [150–153].

Parmacokinetics. The substance is not absorbed after topical administration.

Indications. Topical treatment of mycoses of the skin induced or sustained by fungi such as yeasts and dermatophytes [154]. New formulations for the treatment of vaginal mycoses are in development.

Side Effects. Local irritations and allergic reactions may occur in rare cases and are mainly due to the galenic formulation.

2.2.11. Sulconazole

Sulconazole [*61318-90-9*], 1-[2-[[(4-chlorophenyl)methyl]thio]-2-(2,4-dichlorophenyl)ethyl]-1*H*-imidazole $C_{18}H_{15}Cl_3N_2S$, M_r 460.8.

Sulconazole nitrate [*61318-91-0*], $C_{18}H_{15}Cl_3N_3O_3S$, M_r 524.03, *mp* 130.5–132.0 °C, white or off-white crystalline powder.

Synonym(s). RS-44872, RS-44872-00-10-3 (both mononitrate).

Solubility. 1 part in 3,333 (water), 1 part in 100 (ethanol), 1 part in 130 (acetone), 1 part in 333 (chloroform), 1 part in 2000 (dioxan), 1 part in 71 (methanol), 1 part in 286 (chloromethane), 1 part in 10 (pyridine), 1 part in 2000 (toluene).

Stability. The pure solid substance is stable under normal storage conditions, but shoud be protected from light.

Synthesis. [155]:

Description. See [156–158].

Formulations. 1 % solutions, creams, and ointments.

Trade Names (Sulconazole Mononitrate). Exelderm (Schwarz), MYK (Cassenne), MYK-1 (Will), Sulcosyn (Syntex), Suldicyn (Syntex).

Antimycotic Properties. Sulconazole is a broad-spectrum imidazole antimycotic with activity against almost all pathogenic fungi [159–161].

Pharmacokinetics. The substance is not absorbed after topical administration.

Indications. Topical treatment of mycoses of the skin induced or sustained by fungi such as dermatophytes and yeasts.

Side Effects. Local irritations and allergic reactions may occur in rare cases and are mainly due to the galenic formulation.

2.2.12. Terconazole

Terconazole [*67915-31-5*], *cis*-1-[4-[[2-(2,4-dichlorophenyl)-2-(1*H*-1,2,4-triazol-1-ylmethyl)-1,3-dioxolan-4-yl]methoxy]phenyl]-4-(1-methylethyl)piperazine, $C_{26}H_{31}Cl_2N_5O_3$,

M_r 532.48, *mp* 126.3 °C, crystals from isopropyl ether.

Synonym(s). Triaconazole, R 42470.

Stability. The pure solid substance is stable under normal storage conditions.

Synthesis. [162], [163]:

2,4-Dichloroacetophenone Glycerol

Dioxolane

2-(Bromomethyl)-2-(2,4-dichlorophenyl)-4-(benzoyloxymethyl)-1,3-dioxolane

Description. The triazole antimycotic terconazole was first synthesized at Janssen Pharmaceuticals [164–166].

Formulations. 1 % solutions, powders, ointments, and cream formulations; vaginal pessar (80 mg).

Trade Names. Fungistat (Janssen), Gyno-Terazol (Cilag), Panlomyc (Janssen), Terazol (Cilag, Organon, Ortho), Terconal (Fisons), Tercospor (Cilag).

Antimycotic Properties. Terconazole is a broad-spectrum triazole antimycotic with activity against most species of pathogenic fungi [163].

Pharmacokinetics. After intravaginal application, 5 – 16 % of the dose is aborbed. The substance is extensively metabolized and eliminated via the urine and feces [163].

Indications. Topical treatment of mycoses of the skin induced or sustained by fungi such as dermatophytes and yeasts. In addition, terconazole is indicated for theraphy of vulvovaginal mycoses caused by *Candida* species and *Candida (Torulopsis) glabrata* [167], [168].

Side Effects. *CNS.* After intravaginal application of terconazole, a flu syndrome (fever, headache, hypotension) was observed [169].

Local irritations and allergic reactions may occur in rare cases and are mainly due to the galenic formulation.

2.2.13. Tioconazole

Tioconazole [*65899-73-2*], 1-[2-[(2-chloro-3-thienyl)methyloxy]-2-(2,4-dichlorophenyl)ethyl]-1*H*-imidazole, $C_{16}H_{13}Cl_3N_2OS$, M_r 387.70, crystals.

Synonym(s). TIO, IK 20 349.

Stability. The pure solid substance is stable under normal storage conditions.

Synthesis. [170]:

Description. The imidazole antimycotic tioconazole was first synthesized at Pfizer Pharmaceuticals [171], [172].

Formulations. 1 % solutions, lotions, ointments, and cream preparations for therapy of dermatomycoses; 28 % solutions for onychomycoses; 2 – 6 % cream preparations for vaginal candidiasis.

Trade Names. Dermo-Trosyd (Pfizer), Fungibacid (Asche), Gino-Tralen (Pfizer), Gyno-Trosyd (Mason, Pfizer), Tralen (Pfizer), Trosid (Pfizer), Trosyd (Mason, Pfizer, Roerig), Trosyl (Roerig, Novex, Pfizer), Vagistat (Bristol-Myers-Sqibb), Zoniden (Irbi).

Antimycotic Properties. Tioconazole is a broad-spectrum imidazole antimycotic with activity against almost all species of pathogenic fungi [173–175].

Pharmacokinetics. Tioconazole is normally not absorbed after topical application to the skin [173]. On vaginal application of an ovulum containing 300 mg tioconazole, a serum concentration of 21 µg/mL was observed after 8 h [174].

Indications. Topical treatment of mycoses of the skin induced or sustained by fungi such as dermatophytes and yeasts [176]. In addition, tioconazole is indicated for therapy of vulvovaginal mycoses caused by *Candida* species and *Candida (Torulopsis) glabrata*.

Side Effects. Local irritations such as itching, burning sensations, erythema, and dermatitis, and allergic reactions may occur in rare cases and are mainly due to the galenic formulation [177], [178].

3. Polyene Antimycotics

The mechanism of action of polyene antimycotics is based on the formation of a complex with ergosterol in the fungal plasma membrane. This complex causes changes in the permeability of the plasma membrane, loss of ions and low molcular mass cytoplasmatic components, and inhibition of glycolysis [179]. The effect of polyenes on fungi is antagonized by Ca^{2+}, Mg^{2+}, and sterols in vitro. Further, an antagonism between polyene and azole antimycotics has been observed in several cases, both in vitro

and in vivo. This antagonism can be explained in terms of both substance classes interfering with ergosterol biosynthesis.

The polyenes are primarily fungistatic at concentrations around the MIC level. In vitro fungicidal effects are achieved with 2, 4 or up to 10 times the MIC. The three relevant polyene antimycotics amphotericin B, natamycin (pimaricin), and nystatin show broad-spectrum in vitro antimycotic activity. Amphotericin B is the most potent of these three substances. However, in vivo activity is confined to yeasts, dimorphic (biphasic) fungi, and moulds, including *Aspergillus* species. Generally, the polyenes are less active to mostly ineffective and therefore generally not indicated in the treatment of dermatophytoses.

Polyenes are not absorbed sufficiently, if at all, on oral administration. Parenteral administration causes serious local inflammations. Nystatin and pimaricin are therefore unsuitable for intravenous administration.

3.1. Amphotericin B

Amphotericin B [*1397-89-3*], natural product, 38-membered cyclic lactone, isolated, e.g., from culture filtrates of *Streptomyces nodosus*. There are seven double bonds in the molecule. The keto group in position 1 is cyclized with the hydoxl group in position 35 to form a hemiacetal. The carbon atom at position 33 is attached to the dideoxy sugar mycosamine by a β-glucoside bond. $C_{47}H_{73}NO_{17}$, M_r 924.1, *mp*: does not have an exact melting point and decomposes above 170 °C, amorphous yellow powder.

Synonym(s). RP 17774.

Solubility. Insoluble in water at pH 6 – 7. Solubility in water at pH 2 or pH 11: 0.1 mg/mL. Soluble in aqueous ethanol; DMF: 2 – 4 mg/mL; DMF + HCI: 60 – 80 mg/mL; DMSO: 30 – 40 mg/mL; insoluble in ether, ethyl acetate, or benzene. Soluble in aqueous sodium desoxycholate.

Stability. Amphotericin B is unstable to heat and prolonged exposure to light. It should be stored in the dark and kept refrigerated. In solution it decomposes at pH < 4 and > 10 [180]. Solutions show an optimum stability in a citrate – phosphate buffer at pH 5 – 7 [181–183].

Synthesis. Mostly fermentative from *Streptomyces* species [184]. First isolated from a culture of *Streptomyces nodosus* M4575, an isolate obtained from soil of the Orinoco river region of Venezuela.

Description. The first gereal characterization appeared in 1961 [185]. After some partial structures were determined, the complete structure was published in 1970 [186], and the total synthesis in 1987 [187], [188].

Formulations. For systemic treatment: Ampules à 0.05 g. Liposomal formulations with reduced toxicity [189–191] are available for systemic treatment. For local therapy, amphotericin B formulations such as cream preparations and ointments, lozenge formulations (à 0.1 and 0.01 g), and suspensions (100 mg/mL) are used. Also topical cream formulations additionally containing antibiotics (e.g., neomycine) and/or steroids (e.g., triamcinolone) are on the market.

Trade Names. AmBisome (Vestar), Ampho-Moronal (Bristol-Myers Squibb, Heyden, Squibb), Funganiline (Med. y Prod. Quim.), Fungilin (Bristol-Myers Squibb, Novo Nordisk, Squibb), Fungizone (Bristol-Myers Squibb, Squibb).

Antimycotic Properties. Amphotericin B is a broad-spectrum polyene antimycotic with activity against pathogenic yeasts, moulds, dimorphic fungi, and in vitro also against dermatophytes [192], [193]. MIC values of amphotericin B are summarized in Table 7.

Table 7. MIC values for amphotericin B, nystatin, and pimaricin

Fungus	MIC range, µg/mL		
	amphotericin B	nystatin	pimaricin
Candida species	0.1 – 0.5	1 – 5	1.5 – 10
Cryptococcus neoformans	0.1 – 0.5	0.5 – 4	6 – 12.5
Aspergillus species	0.1 – 0.5	1 – 10	3 – 12
Coccidioides immitis	0.1 – 0.5	0.5 – 1.5	2.5 – 25
Histoplasma capsulatum	0.1 – 1	0.5 – 1	3
Blastomyces species	0.1 – 0.5	0.5 – 1	1.5
Dermatophytes	2 – 4	2 – 10	1.2 – 100

Pharmacokinetics. Amphotericin B is scarcely absorbed after oral application. Therefore, amphtericin B has to be applied by the intravenous route for the treatment of systemic fungal infections [194]. Intravenous administration of 5 – 75 mg/d leads to serum concentrations of 0.14 – 2.39 mg/L 4 h after infusion [194]. The extravascular tissue distribution of amphotericin B is minimal because of cell membrane and lipoprotein binding [195]. The highest amphotericin B tissue concentrations are achieved in the liver and spleen, and also in the lungs and kidneys [196], [197]. Because of its poor penetration of the blood – brain barrier, meningitis and infections of the central nervous system can only be treated intralumbally and/or intrathecally [194]. The metabolization of amphotericin B is still unclear, and no metabolites have been charcterized so far [196]. Only 3 % of the administered dose is found in the urine [198], and 1 – 15 % of the daily dose is eliminated by the biliary – fecal route [197]. Much of the substance is trapped in the organs. Elimination occurs in two phases. The initial half-life is between 1 and 2 d, with a terminal half-life of 15 d [194].

Indications. Amphotericin B is effective in therapy of *Candida* infections, also including generalized and disseminated forms, caused by *Candida albicans* and other pathogenic *Candida* species [199]. Further, amphotericin B is indicated in the therapy of mycotic diseases such as histoplasmosis, sporotrichosis, cryptococcosis, blastomycosis, aspergillosis, zygomycosis, and coccidioidomycosis [200]. Although the substance shows an in vitro activity against dermatophytes, amphotericin B is not indicated in the therapy of dermatophytoses, mostly due to toxicity and stability problems and high cost. In the treatment of generalized mycoses, often a synergistic effect between amphotericin B and fluorocytosine [201], [202], and an antagonistic effect between amphotericin B and azole antimycotics is observed (the latter with the exception of CNS cryptococcosis due to *Cryptococcus neoformans*). Indications and efficacy of amphotericin B are summarized in Table 8. Amphotericin B can be given as a continuous drip infusion, even though serious, and in some cases, irreparable side effects, predominantly to the kidney tubulus, have been observed. Therefore, systemic treatment should be initiated only after exact diagnosis, and the patient should be kept under strict supervision. The optimum dosage for systemic therapy is 1 mg/kg every 24 to 48 h. Despite serious side effects, amphotericin B still remains a drug of choice for treating systemic mycoses.

Table 8. Indications and efficacy of amphotericin B at optimal dosage

Indication	Pathogen	Clinical efficacy
Candidosis	*Candida* species, mostly *C. albicans*	effective in > 50 % of cases
Aspergillosis	*Aspergillus* species except *A. nidulans*	uncertain
Zygomycosis	*Mucor* and *Absidia* species	uncertain
Blastomycoses	*Blastomyces dermatidis, Bl. brasiliensis*	effective in ≈ 50 % of cases
Coccidioidomycosis	*Coccidioides immitis*	effective
Histoplasmosis	*Histoplasma capsulatum*	usually effective

Side Effects. The following side effects have been observed under systemic therapy:

CNS. Fever, vomiting, and chills are observed in about 50 % and seem to be mediated by prostaglandines.

Heart. Rarely, arrythmia is observed under infusion [203].

Circulation. Collapse.

Vessels. Thrombophlebitis at the injection site is requently observed, liposomal formulations show a lower phlebotoxicity [204].

Blood/Spleen. Anemia and thrombocytopenia [204] are rarely observed.

Liver. In some cases, hepatotoxicity was observed.

Kidney. Amphotericin B shows a high degree of nephrotoxicity. Cumulative doses of 4 – 5 g generally cause reversible damage to the kidneys [205]. Higher doses mostly cause an irreversible kidney damage with persisting hypopotassemia, hematuria, proteinuria, and azotemia [203–206]. Therefore, serum potassium, magnesium, and creatinine levels have to be frequently monitored.

In the case of intralumbal and/or intrathecal administration, severe side effects of the central nervous system are common. Liposomal formulation of amphotericin B can reduce toxicity problems [207].
